
Z isomer

1,3-Dichloropropene is obtained as a byproduct in the chlorination of propene (→ Allyl Compounds, Chap. 1.3. [25].

1,3-Dichloropropene is marketed as a mixture containing the inactive 1,2-dichloropropane, or as the pure active substance (mixture of *E* and *Z* isomers). Dichloropropene is used purely as a soil fumigant nematicide (the *Z* isomer is more effective than the *E* isomer) and is used pre-planting to control most species of nematode in deciduous fruit and nuts, citrus fruit, berry fruit, vines, strawberries, and many other crops.
Trade Names. D-D (Cyanamid, Hokko); Telone (DowElanco); Nematox (Siapa).

Metam [*144-54-7*], methyldithiocarbamic acid, $C_2H_5NS_2$, M_r 107.2 and *metam sodium* [*137-42-8*], sodium methyldithiocarbamate, $C_2H_4NNaS_2$, M_r 129.2, sodium metam forms a colorless crystalline dihydrate which decomposes on melting. It is readily soluble

in water, and moderately soluble in acetone, ethanol, and xylene [20, p. 797].

Metam sodium is produced by reaction of methylamine with carbon disulfide and sodium hydroxide [26]. The most common application form of metam sodium is a ca. 30 wt % solution. The action of metham is based on the slow formation of methyl isothiocyanate in the ground, and controls nematodes, soil fungi, weeds, weed seeds, and soil insects.
Trade Names. Vaparn (Zeneca); Arapam (Aragonesas); Trimaton (Elf Atochem); Unifume (Unicrop).

Methyl bromide [*74-83-9*], bromomethane, CH_3Br, M_r 94.9, *mp* −93 °C, *bp* 4.5 °C, vapor pressure 227 kPa (25 °C), is a colorless gas which is readily soluble in many organic solvents [20, p. 824]. Methyl bromide is manufactured from methanol and hydrogen bromide (→ Bromine Compounds, Chap. 1.4.7. [27]. Methyl bromide is a fumigant insecticide and nematicide, and as a multi-purpose fumigant used for insecticidal, acaricidal, and rodenticidal control in mills, warehouses, grain elevators, ships, and in stored products.
Trade Names. Brom-O-Gas, Met-O-Gas 100 (Great Lakes); Haltox (Degeseh).

Methyl isothiocyanate [*556-61-6*], isothiocyanatomethane, C_2H_3NS, M_r 73.1, *mp* 35–36 °C, *bp* 118–119 °C, vapor pressure 2.7 kPa (20 °C), forms colorless crystals which are fairly soluble in water and in many organic solvents [20, p. 827].

CH_3NCS

Methyl isothiocyanate is produced by reaction of methylamine with thiophosgene [28]. Methyl isothiocyanate is a multi-purpose soil fumigant used for control of nematodes, soil fungi, soil insects, and weed seeds.
Trade Name. Trapex (AgrEvo).

4.2. Carbamates

Aldicarb [*116-06-3*], 2-methyl-2-(methylthio)propanal *O*-(methylcarbamoyl) oxime, $C_7H_{14}N_2O_2S$, M_r 190.3, *mp* 98–100 °C, vapor pressure 13 mPa (25 °C), consists of colorless crystals which are fairly soluble in water, readily soluble in acetone, dichloromethane, benzene, xylene, practically insoluble in heptane, and in mineral oils [20, p. 26].

Aldicarb is prepared by treating isobutene with nitrosyl chloride, treating the resulting dimeric adduct with sodium methyl sulfide, and converting the resulting oxime to the carbamate with methyl isocyanate. **Warning:** the dimeric isobutene nitrosochloride is unstable and decomposes explosively at 94 °C. The oxime and end product also decompose vigorously above 140 and 160 °C, respectively. Aldicarb is rapidly oxidized to the corresponding sulfoxide (water solubility > 330 g/L) and slowly to the sulfone [29, 30].

Aldicarb is used as a nematicide, acaricide, and systemic insecticide; it is particularly effective against aphids, white flies (aleyrodids), and leaf minersin a variety of crops.
Trade Name. Temik (Rhône–Poulenc); Sanacarb (Sanachem).

Aldoxycarb [*1646-88-4*] has both insecticidal and nematicidal activity and has been used against a range of pests.

Carbofuran [*1563-66-2*], (2,3-dihydro-2,2-dimethylbenzofuran-7-yl)methylcarbamate, $C_{12}H_{15}NO_3$, M_r 221.3, *mp* 150–152 °C, vapor pressure 2.6 mPa (33 °C), forms colorless crystals which are slightly soluble in water but readily soluble in dichloromethane, isopropyl alcohol, and toluene [20, p. 186].

Carbofuran is prepared by the Claisen rearrangement and cyclization of 2-methallyloxy-1-nitrobenzene to 2,3-dihydro-2,2-dimethyl-7-nitrobenzofuran. Reduction of the nitro compound gives the corresponding aniline, which is diazotized and concentrated by boiling to form the phenol. Reaction with methyl isocyanate gives carbofuran [31]. Carbofuran has insecticidal and nematicidal properties and is used in a wide range of crops.
Trade Names. Furadan, Agrofuran (Sanonda); Curaterr (Bayer); Carbodan (Makhteshim-Agan); Carbosip (Sipcam); Cekufuran (Cequisa); Terafuran (Sanachem).

Cloethocarb [*51487-69-5*] was mainly used as an insecticide.

Oxamyl [*23135-22-0*], *N*,*N*-dimethyl-2-methylcarbamoyloxyimino-2-(methylthio)acetamide, $C_7H_{13}N_3O_3S$, M_r 219.3, *mp* 100–102 °C, vapor pressure 31 mPa (25 °C), consists of colorless crystals which are readily soluble in water, methanol, ethanol, acetone, and fairly soluble in toluene [20, p. 909].

Oxamyl is prepared by chlorination of the oxime of methyl glycolate, reaction with methanethiol and alkali, followed by reaction with dimethylamine, and conversion to the carbamate with methyl isocyanate [32]. Oxamyl is used as an insecticide, acaricide, and nematicide in a wide range of crops. Used as a leaf spray, the compound is also nematicidally active on account of basipetal translocation.
Trade Name. Vydate (Du Pont).

4.3. Organophosphorus Esters

Cadusafos [*95465-99-9*], *S*,*S*-di-*sec*-butyl *O*-ethyl phosphorodithioate, $C_{10}H_{23}O_2PS_2$, M_r 270.4, *bp* 112–114 °C (0.10 kPa), vapor pressure 0.12 Pa (25 °C), is a pale yellow liquid which is moderately soluble in water, and completely miscible with acetone, acetonitrile, dichloromethane, ethyl acetate, toluene, methanol, isopropyl alcohol, and heptane [20, p. 171].

Cadusafos is prepared by treating ethyl dichlorophosphate with *sec*-butanethiol in the presence of a base and under anaerobic conditions [33]. Cadusafos is used as an insecticide and nematicide in bananas, citrus fruits, maize, potatoes, sugar cane, tobacco, and vegetables.
Trade Names. Rugby, Apache (FMC).

Diamidfos [*1754-58-1*] was uses as a nematicide.

Diazinon [*333-41-5*] is mainly used as an insecticide (see → Acaricides, Chap. 3.1.).

Dichlofenthion [*97-17-6*] was used as a nematicide and insecticide.

Ethoprophos [*13194-48-4*], *O*-ethyl *S*,*S*-dipropyl phosphorodithioate, $C_8H_{19}O_2PS_2$, M_r 242.3, *bp* 86–91 °C (25 Pa), vapor pressure 46.5 mPa (26 °C), pale yellow liquid which is moderately soluble in water, readily soluble in acetone, ethanol, xylene, dichloromethane, diethyl ether, ethyl acetate, cyclohexane, and petroleum spirit[20, p. 480].

Ethoprophos is prepared by treating ethyl dichlorophosphate with propanethiol in the presence of sodium hydroxide and under anaerobic conditions [34]. Ethoprophos is a nonsystemic insecticide and nematicide used in a wide variety of crops.
Trade Name. Mocap (Rhône–Poulenc).

Fenamiphos [*22224-92-6*], ethyl 4-methylthio-*m*-tolyl isopropylphosphoramidate, $C_{13}H_{22}NO_3PS$, M_r 303.4, *mp* 49.2 °C, vapor pressure 0.133 mPa (30 °C), forms colorless crystals which are moderately soluble in water, and readily soluble in dichloromethane, isopropyl alcohol, toluene, fairly soluble in hexane [20, p. 503].

Fenamiphos is prepared by condensing 4-methylthio-*m*-cresol with *O*-ethyl *N*-isopropyl phosphoramidochloride, or with ethyl dichlorophosphate followed by reaction with isopropylamine [35]. Fenamiphos is a broad-spectrum, systemic nematicide used in a wide range of crops.
Trade Name. Nemacur (Bayer).

Fensulfothion [*115-90-2*] was used as an insecticide and nematicide.

Fosthiazate [*98886-44-3*], (*RS*)-*S*-*sec*-butyl *O*-ethyl 2-oxo-1,3-thiazoliden-3-ylphosphonothioate, $C_9H_{18}NO_3PS_2$, M_r 183,.3, *bp* 198 °C (0.5 mm Hg), light brown liquid which is fairly soluble in water, and hexane [20, p. 631].

Fosthiazate is produced by treating 2-oxo-3-thiazolidine with *S*-*sec*-butyl *O*-ethyl phosphorochloridothioate in toluene [36]. Fosthiazate is used to control nematodes, aphids, thrips, etc.
Trade Name. Nemathorin (Ishihara Sangyo).

Isazofos [*42509-80-8*], *O*-(5-chloro-1-isopropyl-1*H*-1,2,4-triazol-3-yl) *O*,*O*-diethyl phosphorothioate, $C_9H_{17}ClN_3O_3PS$, M_r 313.7, *bp* 120 °C (130 mPa), vapor pressure 4.3 mPa (20 °C), yellow liquid which is moderately soluble in water, but miscible with organic solvents [20, p. 762].

Isazofos is synthesized by treating ethyl 3-isopropylcarbazate with cyanogen chloride, followed by cyclization with phosgene. Phosphorylation of the triazole with *O*,*O*-diethylthiophosphoryl chloride yields isazofos [37]. Isazofos is a soil-applied nematicide and insecticide with contact and systemic properties for use on bananas, citrus fruits, cotton, leeks, maize, rice, vegetables, sugar cane, and in turf against soil-dwelling insects.
Trade Name. Miral (Novartis).

Phorate [*298-02-2*], see → Acaricides, Chap. 3.1.

Terbufos [*13071-79-9*], *S*-(*tert*-butylthio)-methyl *O*,*O*-diethyl phosphorodithioate, $C_9H_{21}O_2PS_3$, M_r 288.4, *bp* 69 °C (1 Pa), *mp* −29.2 °C, vapor pressure 34.6 mPa (25 °C), is a colorless to pale yellow liquid which is sparingly soluble in water but readily soluble in most common organic solvents [20, p. 1165].

Terbufos is prepared by treating *O*,*O*-diethyldithiophosphoric acid with formaldehyde and *tert*-butanethiol [38]. Terbufos is a nernaticide and insecticide used on bananas and sugar beet.
Trade Name. Counter (Cyanamid); Contraven (Cyanamid, BASF, DowElanco); Cyanater (Siaga); Hunter (United Phosphorus); Testin (Sanonda).

Thionazin [*297-97-2*] was used as a soil insecticide and nematicide.

Triazophos [*24017-47-8*], see → Acaricides, Chap. 3.1.

4.4. Other Nematicides

DCIP [*108-60-1*], bis(2-chloro-1-methylethyl) ether, $C_6H_{12}Cl_2O$, M_r 171.1, *bp* 187 °C (760 mm Hg), light brown oily liquid which is moderately soluble in water [20, p. 330].

$[ClCH_2CH(CH_3)]_2O$

DCIP is produced by treating isopropyl alcohol with anhydrous acid chloride at low temperature [39]. DCIP is used for the control of nematodes and citrus ground mealybug in vegetables, fruit, tobacco, ornamentals, tea, and mulberries.
Trade Name. Nemamort (SDS Biotech).

GY-81 [*7345-69-9*], sodium tetrathio(peroxocarbonate), $CNaS_4$, M_r 186.2, is a hygroscopic orange crystalline solid which is very soluble in water [20, p. 653].

GY-81 is produced by reaction of carbon disulfide with sulfur in alkali ethoxide [40]. GY-81 decomposes in the soil to the broad-spectrum biocide carbon disulfide, it is used as a contact fumigant for the management of grape phylloxera, plant parasitic nematodes and various soil-borne pathogens causing root rot.
Trade Name. Enzone (Unocal).

5. Toxicology

5.1. Fumigants and Other Agents

Chloropicrin [*76-06-2*] [41]

LD_{50} (rat, oral)	250	mg/kg
LC_{50} (mouse, 10-min inhalation)	1.60	mg/L air
LC_{50} (cat, 20-min inhalation)	0.8	mg/L air
LC_{50} (dog, 20-min inhalation)	0.8	mg/L air
LC_{50} (rabbit, 20-min inhalation)	0.8	mg/L air
Rabbit: severe skin irritant		

Dazomet [*533-74-4*] [42]

LD_{50} (rat, oral)	550 – 710	mg/kg
LD_{50} (mouse, oral)	430 – 455	mg/kg
LD_{50} (mouse, dermal)	2400 – 2530	mg/kg
LD_{50} (rat, dermal)	2260 – 2600	mg/kg
LC_{50} (rat, 4-h inhalation)	7.29 to > 8.4	mg/L air
Rabbit: mild eye irritant		
Rabbit: not a skin irritant		
Guinea pig: not a skin sensitizer		
Nonmutagenic		
NOEL/NOAEL:		
Reproduction.		
Rat (2-generation feed)	0.5	$mg\,kg^{-1}\,d^{-1}$ (parental)
	18	$mg\,kg^{-1}\,d^{-1}$ (developmental)
Teratogenicity.		
Rat (gavage)	3	$mg\,kg^{-1}\,d^{-1}$ (maternal and developmental)
Rabbit (gavage)	25	$mg\,kg^{-1}\,d^{-1}$ (maternal)
	12.5	$mg\,kg^{-1}\,d^{-1}$ (developmental)
Chronic.		
Rat (2-year feed)	0.3 – 1.3	$mg\,kg^{-1}\,d^{-1}$
Mouse (78-week feed)	4 – 6	$mg\,kg^{-1}\,d^{-1}$
Dog (one-year feed)	0.5 – 1.5	$mg\,kg^{-1}\,d^{-1}$

1,3-Dichloropropene [*542-75-6*] [20, p. 366]

LD_{50} (rat, oral)	110 – 713	mg/kg
LD_{50} (rat, dermal)	> 1211	mg/L air
LD_{50} (rabbit, dermal)	333 – 540	mg/kg
LC_{50} (rat, 4-h inhalation)	2.70 – 3.07	mg/L air
Rabbit: skin and eye irritant		
NORL/NOAEL:		
Inhalation studies:		
Subchronic.		
Rat (90-d)	0.05	mg/L air
Mouse (90-d)	0.05	mg/L air
Reproduction.		
Rat	0.45	mg/L air
Chronic.		
Rat (2-year)	0.099	mg/L air
Mouse (2-year)	0.025	mg/L air

Ethylene dibromide [*106-93-4*] [43, p. 683]

LD_{50} (rat, oral)	146 – 420	mg/kg	[20, p. 490]
LD_{50} (mouse, oral)	420	mg/kg	[20, p. 490]
LD_{50} (rabbit, oral)	55	mg/kg	
LD_{50} (guinea pig, oral)	110	mg/kg	
LD_{50} (chick, oral)	79	mg/kg	
LD_{50} (rat, dermal)	450	mg/kg	
LD_{50} (rabbit, dermal)	450	mg/kg	
LC_{50} (rat, 7-h inhalation)	0.35	mg/L air	
Rabbit: skin and eye irritant			
ADI: $1.0\,mg\,kg^{-1}\,d^{-1}$			

Metam sodium [*144-42-8*] [20, p. 797]

LD_{50} (rat, oral)	1700 – 1800	mg/kg
LD_{50} (mouse, oral)	285	mg/kg
LD_{50} (rat, oral)	97	mg/kg for isothiocyanate formed in soil
LD_{50} (rabbit, dermal)	1300	mg/kg
LC_{50} (rat, 4-h inhalation)	> 4.7	mg/L air

Rabbit: skin irritant
Rabbit: severe eye irritant
NOEL/NOAEL:
Subchronic.

Rat (65-d (6-h d^{-1}, 5-d $week^{-1}$))	0.045	mg/L air

Methyl bromide [*74-83-9*] [20, p. 824]

LC_{50} (rat, 4-h inhalation)	3.03	mg/L air
LC_{50} (rat, 8-h inhalation)	2.1	mg/L air
LC_{50} (mouse, one-h inhalation)	8.4	mg/L air

Rabbit: skin and eye irritat

Methyl isothiocyanate [*556-61-6*] [44]

LD_{50} (rat, oral)	72 – 175	mg/kg
LD_{50} (mouse, oral)	90 – 104	mg/kg
LD_{50} (rat, dermal)	2780	mg/kg
LD_{50} (mouse, dermal)	1870	mg/kg
LD_{50} (rabbit, dermal)	263	mg/kg
LC_{50} (rat, 1-h inhalation)	1.9	mg/L air

Rabbit: moderate skin irritant
Rabbit: severe eye irritant
Guinea pig: weak skin sensitizer
Nonmutagenic
NOEL/NOAEL:
Reproduction.

Rat (2-generation, drinking water)	1	mg kg^{-1} d^{-1} (parental)
	5	mg kg^{-1} d^{-1} (developmental)

Teratogenicity.

Rat (gavage)	5	mg kg^{-1} d^{-1} (maternal and developmental)
Rabbit (gavage)	3	mg kg^{-1} d^{-1} (maternal)
	5	mg kg^{-1} d^{-1} (developmental)

Chronic.

Rat (2-year, drinking water)	0.514 – 0.746	mg kg^{-1} d^{-1}
Mouse (106-week, drinking water)	3.30 – 3.66	mg kg^{-1} d^{-1}
Dog (one-year, gavage)	0.4	mg kg^{-1} d^{-1}

5.2. Carbamates

Aldicarb [*116-06-3*] [45]

LD_{50} (rat, oral)	0.46 – 1.20	mg/kg
LD_{50} (mouse, oral)	0.38 – 1.5	mg/kg
LD_{50} (guinea pig, oral)	1.0	mg/kg
LD_{50} (rabbit, oral)	1.3	mg/kg
LD_{50} (rat, dermal)	> 10	mg/kg
LD_{50} (rabbit, dermal)	> 10	mg/kg

Rabbit: nonirritating to skin and eyes
Guinea pig: not a skin sensitizer
Nonmutagenic
NOEL/NOAEL:
Reproduction.

Rat (feed)	0.3	mg kg^{-1} d^{-1}

Teratogenicity.

Rat (gavage)	0.125	mg kg^{-1} d^{-1} (maternal)
	0.25	mg kg^{-1} d^{-1} (developmental)

Chronic.

Rat (93-d feed)	0.1	mg kg^{-1} d^{-1}
Mouse (103-week feed)	0.9	mg kg^{-1} d^{-1}
Dog (one-year feed)	0.05	mg kg^{-1} d^{-1}
Human (single oral dose)	0.025	mg kg^{-1} d^{-1}

ADI: 0.003 mg kg^{-1} d^{-1}

Carbofuran [*1563-66-2*] [46]

LD_{50} (rat, oral)	6.0 – 14.4	mg/kg
LD_{50} (mouse, oral)	14.4	mg/kg
LD_{50} (dog, oral)	15 – 19	mg/kg
LD_{50} (cat, oral)	2.5 – 3.5	mg/kg
LD_{50} (chick)	2.5 – 38.9	mg/kg
LD_{50} (rabbit, oral)	7.5	mg/kg
LD_{50} (guinea pig)	9.2	mg/kg
LD_{50} (rat, dermal)	> 500	mg/kg
LD_{50} (rabbit, dermal)	> 46.4	mg/kg
LC_{50} (rat, 4-h inhalation)	75 – 88	µg/L air

Rabbit: mild skin and eye irritant
Nonmutagenic
NOEL/NOAEL:
Reproduction.

Rat (3-generation feed)	1.2	mg kg^{-1} d^{-1} (parental and developmental)

Teratogenicity.

Rat (feed)	1.5	mg kg^{-1} d^{-1} (maternal)
	4.4	mg kg^{-1} d^{-1} (developmental)
Rabbit (gavage)	0.5	mg kg^{-1} d^{-1} (maternal and developmental)

Chronic.

Rat (2-year feed)	1	mg kg^{-1} d^{-1}
Mouse (2-year feed)	28	mg kg^{-1} d^{-1}
Dog (one-year feed)	0.25	mg kg^{-1} d^{-1}

ADI: 0.002 mg kg^{-1} d^{-1}

Oxamyl [*23135-22-0*] [47]

LD_{50} (rat, oral)	2.5 – 16	mg/kg
LD_{50} (mouse, oral)	2.3 – 3.3	mg/kg
LD_{50} (guinea pig, oral)	7.1	mg/kg
LD_{50} (rat, dermal)	> 1200	mg/kg
LD_{50} (rabbit, dermal)	130	mg/kg
LC_{50} (rat, 4-h inhalation)	0.12 – 0.17	mg/L air

Rabbit: mildly irritating to skin and eyes
Guinea pig: not a skin sensitizer
Nonmutagenic
NOEL/NOAEL:
Reproduction.

Rat (3-generation feed)	2.5	mg kg^{-1} d^{-1} (parental and developmental)

Teratogenicity.		
Rat (gavage)	ca. 4	$mg\,kg^{-1}\,d^{-1}$ (maternal)
	ca. 20	$mg\,kg^{-1}\,d^{-1}$ (developmental)
Rabbit (feed)	ca. 1	$mg\,kg^{-1}\,d^{-1}$ (maternal)
	2	$mg\,kg^{-1}\,d^{-1}$ (developmental)
Chronic.		
Rat (2-year feed)	2.5	$mg\,kg^{-1}\,d^{-1}$
Mouse (2-year feed)	3.6	$mg\,kg^{-1}\,d^{-1}$
Dog (2-year feed)	2.5	$mg\,kg^{-1}\,d^{-1}$

ADI: $0.03\,mg\,kg^{-1}\,d^{-1}$

5.3. Organophosphorus Esters

Cadusafos [*95465-99-9*] [48]

LD_{50} (rat, oral)	39 – 132	mg/kg
LD_{50} (mouse, oral)	71	mg/kg
LD_{50} (rabbit, dermal)	11	mg/kg
LC_{50} (rat, 4-h inhalation)	0.032	mg/L air

Rabbit: eye irritant
Rabbit: slightly skin irritant
Nonmutagenic
NOEL/NOAEL:

Reproduction.		
Rat (2-generation feed)	30	$\mu g\,kg^{-1}\,d^{-1}$ (parental and developmental)
Teratogenicity.		
Rat (gavage)	2	$mg\,kg^{-1}\,d^{-1}$ (maternal)
	6	$mg\,kg^{-1}\,d^{-1}$ (developmental)
Rabbit (gavage)	0.3	$mg\,kg^{-1}\,d^{-1}$ (maternal and developmental)
Chronic.		
Rat (2-year feed)	50	$\mu g\,kg^{-1}\,d^{-1}$
Mouse (2-year feed)	89	$\mu g\,kg^{-1}\,d^{-1}$
Dog (capsule)	0.1	$mg\,kg^{-1}\,d^{-1}$

ADI: $0.0003\,mg\,kg^{-1}\,d^{-1}$

Ethoprophos [*13194-48-4*] [49]

LD_{50} (rat, oral)	33 – 62	mg/kg
LD_{50} (mouse, oral)	18 – 31	mg/kg
LD_{50} (rabbit, oral)	55	mg/kg
LD_{50} (rat, dermal)	226	mg/kg
LD_{50} (pig, dermal)	327	mg/kg
LD_{50} (rabbit, dermal)	26	mg/kg
LC_{50} (rat, 4-h inhalation)	0.123	mg/L air

Rabbit: skin and eye irritant
Nonmutagenic
NOEL/NOAEL:

Chronic.		
Rat (2-year feed)	0.05	$mg\,kg^{-1}\,d^{-1}$
Mouse (2-year feed)	0.035	$mg\,kg^{-1}\,d^{-1}$
Dog (one-year feed)	0.025	$mg\,kg^{-1}\,d^{-1}$

ADI: $0.0003\,mg\,kg^{-1}\,d^{-1}$

Fenamiphos [*22224-92-6*] [50]

LD_{50} (rat, oral)	2.4 – 19.4	mg/kg
LD_{50} (mouse, oral)	22.7	mg/kg
LD_{50} (guinea pig, oral)	56 – 100	mg/kg
LD_{50} (rabbit, oral)	10 – 17.5	mg/kg
LD_{50} (cat, oral)	10	mg/kg
LD_{50} (god, oral)	ca. 10	mg/kg
LD_{50} (chick, oral)	5.3 – 12	mg/kg
LD_{50} (rat, dermal)	72 – 92	mg/kg
LD_{50} (rabbit, dermal)	178 – 225	mg/kg
LC_{50} (rat, 4-h inhalation)	110 – 150	µg/L air

Rabbit: mild eye irritant
Rabbit: minimal skin irritant
Guinea pig: mild skin sensitizer
Nonmutagenic
NOEL/NOAEL:

Reproduction.		
Rat (2-generation feed)	0.17	$mg\,kg^{-1}\,d^{-1}$ (parental)
	0.64	$mg\,kg^{-1}\,d^{-1}$ (developmental)
Teratogenicity.		
Rat (gavage)	1	$mg\,kg^{-1}\,d^{-1}$ (maternal)
	3	$mg\,kg^{-1}\,d^{-1}$ (developmental)
Rabbit (gavage)	0.1	$mg\,kg^{-1}\,d^{-1}$ (maternal)
	0.3	$mg\,kg^{-1}\,d^{-1}$ (developmental)
Chronic.		
Rat (2-year feed)	0.46	$mg\,kg^{-1}\,d^{-1}$
Mouse (20-month feed)	0.3	$mg\,kg^{-1}\,d^{-1}$
Dog (one-year feed)	0.083	$mg\,kg^{-1}\,d^{-1}$

ADI: $0.0008\,mg\,kg^{-1}\,d^{-1}$

Fosthiazate [*98886-44-3*] [20, p. 631]

LD_{50} (rat, oral)	57 – 73	mg/kg
LD_{50} (rat, dermal)	861 – 2396	mg/kg
LC_{50} (rat, 4-h inhalation)	0.588	mg/L air

Rabbit: nonirritating to skin and eyes
Guinea pig: skin sensitizer

Isazofos [*42509-80-8*] [20, p. 726]

LD_{50} (rat, oral)	40 – 60	mg/kg
LD_{50} (rat, dermal)	118 – > 3100	mg/kg
LC_{50} (rat, 4-h inhalation)	0.24	mg/L air

Rabbit: mild skin irritant
Rabbit: very slight eye irritant

Subchronic.		
Rat (90-d feed)	0.2	$mg\,kg^{-1}\,d^{-1}$
Dog (90-d feed)	0.05	$mg\,kg^{-1}\,d^{-1}$

Phorate [*298-02-0*], see→ Acaricides

Terbufos [*13071-79-9*] [51]

LD_{50} (rat, oral)	1.6	mg/kg
LD_{50} (mouse, oral)	5.0 – 9.2	mg/kg
LD_{50} (rabbit, oral)	1.6	mg/kg
LD_{50} (rat, dermal)	0.97 – 9.8	mg/kg
LD_{50} (rabbit, dermal)	0.81 – 1.0	mg/kg
LC_{50} (rat, 4-h inhalation)	6.1	µg/L air
Nonmutagenic		
NOEL/NOAEL:		
Reproduction.		
Rat (3-generation feed)	0.016 – 0.035	$mg\,kg^{-1}\,d^{-1}$
Teratogenicity.		
Rat (gavage)	> 0.20	$mg\,kg^{-1}\,d^{-1}$
Rabbit (gavage)	0.2	$mg\,kg^{-1}\,d^{-1}$ (maternal and developmental)
Chronic.		
Rat (2-year feed)	0.01 – 0.013	$mg\,kg^{-1}\,d^{-1}$
Mouse (18-month feed)	0.9	$mg\,kg^{-1}\,d^{-1}$
Dog (one-year feed)	0.06	$mg\,kg^{-1}\,d^{-1}$
ADI: $0.0002\,mg\,kg^{-1}\,d^{-1}$		

Triazophos [*24017-47-8*], see→ Acaricides

5.4. Other Nematicides

DCIP [*108-60-1*] [20, p. 339]

LD_{50} (rat, oral)	503	mg/kg
LD_{50} (mouse, oral)	530 – 599	mg/kg
LD_{50} (rat, dermal)	> 2000	mg/kg
LC_{50} (rat, 4-h inhalation)	12.8	mg/L air
LC_{50} (mouse, 4-inhalation)	12.8	mg/L air
NOEL/NOAEL:		
Chronic.		
Rat (2-year feed)	13.4	$mg\,kg^{-1}\,d^{-1}$
ADI: $0.13\,mg\,kg^{-1}\,d^{-1}$		

GY-81 [*7345-69-9*] [20, p. 653]

LD_{50} (rat, oral)	631	mg/kg
LD_{50} (rabbit, dermal)	> 2000	mg/kg
LC_{50} (rat, 4-h inhalation)	3.17 – 4.73	mg/L air
Rabbit: moderate eye irritant		
Rabbit: severe skin irritant		
Guinea pig: not a skin sensitizer		
Nonmutagenic		
ADI: $6\,mg\,kg^{-1}\,d^{-1}$

1. Introduction

Most drugs or toxins act on the nervous system in a highly specific way [1–7]. In many cases the particular subsystem or component (e.g., enzyme, ion channel, or transmitter receptor) with which the drug interacts is known precisely. In other cases, the target may be unidentified, but research into the mode of action of the drug, toxin, or toxic substance is best planned on the assumption that the action is specific, and a clue will often be provided by the symptoms that the agent produces in animals or humans. The nonmetabolized gaseous anesthetics (→ Anesthetics, General) are one of the few classes of pharmacological agents to act in a more generalized way on nerve cells but here too their mode of action is to selectively induce biophysical changes in nerve cell membranes which block their excitability, rather than to exert a general effect on the whole cell.

The purpose of this article is to summarize what is known about the organization and function of the nervous system, its chief subsystems and components down to the molecular level in order to provide a background for the following articles on specific topics in neuropharmacology:

Analeptics
Analgesics and Antipyretics
Anesthetics, General
Anti-Obecity Drugs
Antiarrhythmic Drugs
Antiasthmatic Agents
Antiemetics
Antiepileptics

2. Types of Neural Cells

The cells making up nervous tissue can be divided broadly into two types: *nerve cells* (*neurons*) whose task is the transmission and processing of information, and *glia*, to which an insulating and supporting role is assigned (Fig. 1). Within these two categories are many subtypes whose classification is based both on structure and function.

Figure 1. Types of neurons (A – C) and glia (D – F)
Neurons (Golgi staining): A) Pyramidal neuron with cell body (a), axon (b), and dendrites (c); B) Basket cell; C) Bipolar cell
Glia: D) Astrocyte; E) Oligodendrocyte; F) Microglia

2.1. Neurons

A primary distinction can be made between sensory, motor, and interneurons. In the peripheral nervous system (Section 3.1), *sensory neurons* are linked to a variety of sensors (sensory receptors) by which different sensations (touch, pain, heat, cold, pressure, tension, sound, light, smell, taste) and certain internal parameters (such as blood oxygen and carbon dioxide tension) are converted into trains of nerve impulses that convey information about the internal and external environment to the central nervous system (CNS), often through ascending sensory or afferent pathways involving several neurons. By contrast, *motor neurons*, usually under the control of descending or efferent pathways, convey signals to and stimulate effector cells (muscle or gland cells) causing muscles to contract or gland cells to secrete physiologically active substances (hormones, enzymes).

The constant flow of information conveyed by afferent impulses needs to be processed before it can result in effective action. This is achieved by *interneurons* that are often arranged in complex repetitive patterns which resemble the logic units of computer circuits. However, although the nervous system may be thought of as a biological computer regulating and optimizing the responses of the organism to changes in its environment, any close comparison with man-made computers reveals a fundamental difference: the nervous system is not digitalized. It performs numerical computations slowly and with difficulty but is excellent at pattern recognition, association, learning and memory, though again, not of the computational type.

The morphology of nerve cells is elegantly displayed at the light-microscopic level by silver staining, a technique originally devised by C. Golgi (1843 – 1926). In this method only a few cells are stained in a given section of tissue, but the stain spreads until the whole neuron is displayed with all its ramifications (Fig. 1). Cells can then be classified according to their morphology: *pyramidal cells* (Fig. 1 A) are a type of efferent cell with prominent triangular cell bodies; *basket* (Fig. 1 B) and *stellate* (star-shaped) cells are interneurons with bushy processes resembling the wickerwork of a basket or the rays of a star, respectively.

All neurons possess a cell body, which contains a prominent *nucleus* surrounded by *cytoplasm* (perikaryon); in addition almost all neurons send out several or many processes known as *dendrites* (from their resemblance to the branches of trees) and a single process known as an axon. The dendrites and cell body collectively form a receptive field which receives contacts from the axons of neighboring cells. The axon conveys impulses arising from the

convergence of this receptive field to the target cell–another nerve cell or effector (muscle or gland) cell. In sensory cells a dendrite and axon may fuse to form a bipolar cell; impulses generated by receptors attached to the dendrite are picked up by the axon, bypassing the peripherally placed cell body (Fig. 1 C). Towards its terminal the axon may branch several times before terminating on another cell; it may also form swellings or *varicosities* along its length which are in close contact with the target cells. Within the neuron, information is conducted by nerve impulses–self-propagating waves of ion flux that can be detected by minute accompanying fluctuations in membrane potential (Section 4.2). The transmission of information between neurons is brought about by the release of chemical transmitter substances (*neurotransmitters*) from stores in the axon terminal or varicosity (Chap. 5). Neurotransmitters are released by the arrival of a nerve impulse and are of two types–low molecular mass compounds such as acetylcholine and noradrenaline (Section 5.2.1) or neuropeptides (Section 5.2.2); they interact with *receptors* on the cell membrane of the target cell and induce nerve impulses in it. Many drugs owe their effect to their ability to selectively bind to these receptors (Section 5.3.3). The complex of nerve axon termination together with the region of the cell membrane of the target cell immediately apposed to it is known as a *synapse*, a word coined by C.S. Sherrington (1857 – 1952) from two Greek words meaning a "clasping together".

Because so many drugs and toxins act by interfering with synaptic transmission, the synapse has sometimes been called "the Achilles heel" of the nervous system.

2.2. Glia

Glial cells can also be classified on the basis of morphology and function. Three main types are recognized in the CNS: astrocytes, oligodendrocytes, and microcytes. In the PNS, Schwann cells are the peripheral counterparts of oligodendrocytes.

Glial cells were originally regarded as the neural counterpart of connective tissue and as the glue (Greek glía) holding the tissue together. Embryological studies showed that astrocytes and oligodendrocytes, like neurons, are of ectodermal, not mesodermal origin; microglia, however, are derived from mesoderm, like connective tissue.

Astrocytes are star-shaped cells with many radiating processes (Fig. 1 D). The processes may form end-feet applied to brain capillaries and so contribute to the structural and functional barrier between the brain and the blood known as the *blood – brain barrier* or they may surround nerve cells in a manner suggesting a supportive or service function. Much evidence indicates that astrocytes regulate the environment of nerve cells by controlling the extracellular concentrations of hydrogen and potassium ions and chemical transmitters, and by releasing trophic factors essential for the survival of neurons.

Oligodendrocytes. The primary function of these cells (Fig. 1 E) in the CNS and of their counterparts, the *Schwann cells*, in the PNS is to provide an insulating wrapping around axons. This wrapping known as *myelin* is applied in segments (Fig. 2); the short, poorly insulated spaces between segments are known as nodes of Ranvier after their discoverer, L.A. Ranvier (1835 – 1922). The segmental character of this insulation confers an important advantage on the neuron; propagated nerve impulses are forced to jump from one node to the next, a phenomenon known as *saltatory conduction*, and this greatly speeds up nerve conduction.

Figure 2. Myelinated and unmyelinated axons

Microcytes (Fig. 1 F) are wandering cells that invade injured or inflamed regions of the nervous system from the blood stream and remove dead cells and tissue debris by phagocytosis. They are not present in healthy nervous tissue in significant numbers.

Figure 3. Subdivisions of the vertrebrate nervous system
[a] These portions of the peripheral nervous system are collectively referred to as the somatic nervous system. [b] Often classified as the afferent portion of the autonomic nervous system. [c] The retina is often regarded as a peripheral extension of the CNS.

3. Evolution and Organization of the Vertebrate Nervous System

3.1. Evolution and Main Subdivisions

The simplest vertebrate nervous system is seen in fish, amphibia, and reptiles. Birds and mammals represent separate developments from primitive reptilian forms, mainly characterized by a relative expansion of the parts of the brain concerned with sensory processing and motor agility. Nevertheless, the basic plan of all vertebrate nervous systems is similar (Fig. 3) being divided into the *central nervous system* (CNS), comprising the brain and spinal cord, and the *peripheral nervous system* (PNS), comprising the *somatic nerves* (those innervating the voluntary skeletal musculature), the *autonomic nerves* (those innervating glands and the smooth involuntary musculature of the viscera and blood vessels), and the nerves from the organs of special senses. An alternative, more functional classification of the PNS distinguishes between sensory (afferent) and motor (efferent) nerves. The *sensory nerves* mediate information from the special senses, the somatic (skeletal) musculature, and the viscera. The *motor nerves* induce the contraction of skeletal muscle and control the hollow organs of the body and the glands, the latter being termed *autonomic nerves*. These nerves are further subdivided into *sympathetic* and *parasympathetic*. The *sympathetic nervous system* prepares the body for emergencies: the blood supply to the muscles, heart, and brain is increased by dilatation of their blood vessels, while that to the skin and viscera is reduced by vasoconstriction. The heart beats faster, the urinary and rectal outlets are blocked by contraction of their sphincters, intestinal movement and alimentary secretion are stopped, and blood sugar is raised. By contrast the *parasympathetic system* restores bodily function when the crisis is over. Wastes are eliminated by the relaxation of the appropriate sphincters, blood pressure and heart-rate fall, and alimentary function is resumed. Many drugs block (antagonists) or stimulate (agonists) the action of the transmitters involved (→ Parasympatholytics and Parasympathomimetics ; → Sympatholytics and Sympathomimetics).

The anatomy of the sensory and somatic motor systems is relatively simple (Fig. 4 A). Sensory nerves derived from bipolar neurons (Section 2.1) enter the spinal cord through the dorsal (posterior) roots; their cell bodies are located in the dorsal root ganglia. The motor nerves leave the spinal cord through the ventral (anterior) roots; their cell bodies are located in the ventral columns of the spinal cord, protuberances of neuron-rich grey matter jutting out from the central mass of grey matter in the spinal cord.

Figure 4. The relationship of the peripheral nervous system to the spinal cord
A) Somatic system: sensory nerves from muscle receptors form a two-neuron arc with a motor neuron (motoneuron) on the same side and inhibit a motor neuron on the opposite side via an inhibitory interneuron, thus forming a three-neuron arc.
B) Autonomic system: continuous lines indicate visceral afferents, preganglionic sympathetic, and postganglionic; dashed lines indicate preganglionic parasympathetic.
The transmitters utilized (Section 5.2) are shown in boxes; ACh = acetylcholine, NA = noradrenaline, SP = substance P. In reality both systems run together in each root and bilaterally; they are shown separately and unilaterally for clarity.

The autonomic outflow is more complex (Fig. 4 B). Motor nerves issuing from the ventral roots enter ganglia arranged in chains on either side of the backbone. Some (the *preganglionic sympathetic* nerves) make contact with nerve cell bodies in these ganglia. The axons of these ganglion cells (the *postganglionic sympathetic* nerves) provide the sympathetic innervation to the heart, viscera, and blood vessels. Other preganglionic nerves (the *preganglionic parasympathetic* nerves) travel through the ganglia, usually accompanying the postganglionic sympathetic innervation to the heart, viscera, and blood vessels, and eventually making contact with ganglion cells nearer or in the target organs themselves. These cells provide the *postganglionic parasympathetic* innervation. How these connections were worked out is explained in Section 5.1. Brain weight is not a good guide to the degree of evolution of the nervous system since large animals have large brains but may show a behavior no more complex than that of their smaller congeners. The larger brains of large members of a particular family or order contain more glial cells, not necessarily more neurons. To accommodate the increased surface area of larger brains, the outer layers (the *cortex*) are thrown into folds; this is particularly obvious in the human brain, where, compared to other animals, there is in addition a net increase (though not as large as is often supposed) in cortical mass relative to whole brain mass.

Another criterion of development is the relative volume of the hind-brain (cerebellum), a part of the brain concerned with the performance of skilled acts. Originally evolved to control swimming movements in fish, it shows marked development in birds and mammals, especially primates.

3.2. Patterns of Neuronal Integration

3.2.1. The Reflex Arc

The unit of integrated action in the nervous system is the *reflex*. The study of reflexes was begun by SHERRINGTON [8] in decapitated (spinal) cats, maintained by artificial respiration and warmth. Such preparations show integrated responses to stimuli of a quasi-mechanical kind– the foot is sharply withdrawn in response to a prick on the foot pad while the contralateral limb extends to support the body (nociceptive reflex), a limb offers resistance to being pulled (stretch reflex) or jerks when a tendon at the knee or ankle is suddenly stretched by tapping (knee or ankle

jerk); stepping movements can be elicited. Muscular movements involve the relaxation of antagonists (muscles opposing a limb movement) when agonists (muscle causing a movement) contract and, very often, compensating movements on the opposite side.

SHERRINGTON grasped that the simplest integrative unit consisted of a *two-neuron reflex arc*, comprising an afferent sensory neuron synapsing with a motor neuron (Fig. 4 A). Thus, in the stretch reflex, stretching a muscle generates impulses from muscle stretch receptors which are conducted to synapses on motor neurons in the spinal cord and cause a reflex contraction of the muscle from which the impulses originate.

To explain the relaxation of antagonists, SHERRINGTON introduced the concept of *central inhibition*, whereby some synapses activated by incoming impulses inhibit firing of a motor neuron. Normally all motor nerves to muscles generate impulses at a low rate, thus generating the tension (muscle tone) needed to maintain posture; inhibition of a motor neuron to an antagonist muscle thus causes it to relax. Reciprocal excitation and inhibition were invoked to explain the compensatory movements of limbs on the opposite side of the body in the nociceptive and stepping reflexes: sensory impulses would activate agonists and inhibit antagonists on one side of the cord, but activate antagonists and inhibit agonists on the other side.

Careful analysis of the speed of reflex activation and inhibition of motor neurons showed that inhibitory reflex action involves a three-neuron arc with an inhibitory interneuron inserted between the sensory input and motor output (Fig. 4 A). This interneuron is activated by the afferent sensory signal and inhibits the motor neuron. The rate of firing of stretch receptors in muscle can be adjusted by the amount of contraction occurring in the fine muscle fibers (muscle spindles) to which they are attached. These can be adjusted independently of surrounding muscle fibers by the so-called γ-motor neurons (Fig. 5).

Such systems are now familiar to engineers as servomechanisms embodying negative feedback loops, but were first discovered by physiologists.

Figure 5. Simplified scheme showing main systems involved in posture and movement

Figure 6. Sketches of human brain anatomy to illustrate the location of pyramidal, extrapyramidal, and limbic systems described in text
A) Side view of the human brain; B, C) Transverse sections along the lines in A marked X and Y, respectively
A, B) Shaded areas show structures involved in voluntary movement: a) Motor cortex containing pyramidal cells; (b – d) Basal ganglia (extrapyramidal tract); b) Caudate nucleus; c) Putamen; d) Globus pallidus; e) Cerebellum
C) Black regions are structures involved in the limbic system: f) Olfactory cortex; g) Hippocampus; h) Thalamus; i) Hypothalamus; j) Part of basal ganglia (pallidum)
For clarity, structures are shown on one side only but are actually on both sides. Arrows in A show view-points of sections.

3.2.2. Voluntary Movement

In the conscious animal muscular movement is under voluntary control, and occurs smoothly and effortlessly in spite of the vast number of adjustments that have to be made. Figures 5 and 6 summarize the main pathways involved. Playing onto the repertoire of spinal reflexes in this systems analysis are three pathways:

1) the direct pathway of the *pyramidal tract* (Fig. 6 B, a) (so called because it originates in large neurons in the part of the cortex controlling movement whose cell bodies are shaped like a pyramid; Fig. 1 A)
2) the *extrapyramidal tract* operating through a set of well defined nuclei (conglomerations of neurons) below the cortex (Fig. 6 B, b – d), and
3) the hindbrain or *cerebellum* (Fig. 6 A, e), which performs the "staff work" for a skilled movement.

Broadly, the extrapyramidal tract is involved in the control of posture and the cerebellum in the programming of skilled action. Volition seems to act through the premotor cortex. The unit of integrated activity is the spinal reflex (Fig. 4 A). Thick lines in Figure 5 indicate the circuits involved in the preparation for voluntary movement, thin lines the evolving muscular response. Diseases (Parkinsonism, Huntington's chorea) which affect the extrapyramidal system cause postural defects, difficulty in initiating movements, tremor at rest (Parkinsonism), or uncontrolled movements at rest (chorea). Damage to the cerebellum causes intention tremor and clumsy execution of movement.

Variations in the repertoire of skilled acts between animals (e.g., a cat and a chimpanzee) are largely caused (1) by the differing extents to which individual muscles or muscle groups are represented in the cortex, and (2) the degree of control over individual spinal motor neurons exerted by the cortical tracts. Strychnine is a specific blocker for inhibitory synapses (which are described in detail in Section 5.2). The painful cramps caused by its injection are due to the failure of central inhibition as antagonists pull against agonists.

The extrapyramidal tract seems particularly sensitive to degenerative diseases and drugs, some of which mimick the symptoms of such diseases while others alleviate them. Such phenomena require an understanding of the synaptic transmitters involved and will be discussed in Section 5.2.1. The transmitter dopamine plays a key role in this system.

3.2.3. The Limbic System

The limbic system is the term often used to denote those (often phylogenetically old) parts of the brain concerned with feeling and emotion (Fig. 6 C). It is much less clearly defined and

well understood than the motor system described in Sections 3.2.1 and 3.2.2. Two well-defined cortical areas, the olfactory cortex (a phylogenetically old part of the cortex concerned with smell) and the hippocampus (also concerned with memory), are involved, as well as various subcortical nuclei located in the thalamus, hypothalamus (also concerned with nervous control of many bodily functions), and the basal ganglia (also concerned with movement). Probably all the brain structures concerned with visceral control, together with their links to the parts of the brain concerned with cognition, learning, memory, and voluntary movement can be regarded as part of the limbic system. Integrated reactions indicative of rage, fear, aggression, or pleasure can be elicited in animals by local stimulation of certain subcortical limbic structures, particularly the hypothalamus, thus providing experimental justification for the concept of the limbic system. Derangements in the limbic system are believed to be involved in psychoses such as schizophrenia and in various forms of depression (→ Psychopharmacological Agents).

3.2.4. The Ascending Reticular Activation System

This system is phylogenetically old and is located in the brain stem with projections to almost all the subcortical nuclei and the brain cortex. It is believed to "activate" higher centers involved in attention, awareness, and the conscious state but is also thought to be active in the rapid eye movement phase of sleep (REM sleep). Many of the neurons forming this system use acetylcholine as their transmitter and they activate largely by suppressing inhibition (Section 5.2.1). Other important central cholinergic pathways are those arising in the basal nucleus of Meynert (nucleus basalis magnocellularis) projecting to the cortex, and the cholinergic input to the hippocampus which arises in the septum [4]. In several degenerative diseases of the nervous system (e.g., Alzheimer's disease, Parkinsonian dementia) the cholinergic neurons of the nucleus basalis are among the first to degenerate.

4. Techniques for Investigating the Nervous System

The nervous system may be investigated morphologically, physiologically, biochemically, and pharmacologically. Each approach has its advantages and limitations and only a combined approach can give the detailed knowledge needed for complete understanding.

4.1. Neuroanatomy

Neuroanatomy provides a basically static view of the nervous system; only with difficulty can series of static images be assembled into sequences from which the underlying dynamic events can be inferred.

Dissection. Gross dissection of the nervous systems of vertebrates reveals many similarities and homologies of structure with an increasing complexity of organization as the evolutionary tree is ascended, culminating in humans. The macroscopic components of the brain with their areas of grey (neuron-rich) and white (myelin-rich) matter are given fanciful names based on their appearance (e.g., hippocampus, caudate nucleus) or more logical ones based on location (e.g., temporal lobe) or known function (e.g., motor cortex).

Light Microscopy. Histology at the light microscopic level reveals individual neuronal and glial cells and gives some clues as to connections. Histochemical methods, based on staining for specific enzymes or antigens, reveal differences within the broad classes of neurons or glia which may have important functional significance. Here, a powerful new technique, *in situ* hybridization with a DNA preparation (cDNA) complementary to a messenger RNA (mRNA) coding for a specific functional protein, is providing valuable information unobtainable in other ways. Microinjection of a strongly fluorescent dye (e.g., procyon yellow) into a neuron often vividly reveals connexions, thus supplementing older methods based on sectioning fiber tracts and tracing their subsequent degeneration.

Electron Microscopy. In the CNS, presynaptic nerve terminals often appear under the electron microscope as club-like expansions (ca.

0.5 µm in diameter) of the fine (0.2 µm diameter) terminal axonal branches (Fig. 7 A). There is a distinct electron-lucent gap between the pre- and postsynaptic membranes, the purpose of which may be to shunt the potentials associated with the arrival of a nerve impulse and to prevent them invading the postsynaptic membrane, thus altering its excitability. This allows synaptic transmission to be purely chemical in character. In some rare synapses where there is evidence of electrotonic transmission, this "synaptic gap" does not appear and pre- and postsynaptic membranes are closely apposed.

The presynaptic terminal cytoplasm is packed with vesicular organelles of equal size (ca. 0.05 µm in diameter). These are referred to as *synaptic vesicles*. Their function is to store transmitter and to release it when the nerve terminal is invaded by a nerve impulse, by temporarily fusing with the terminal plasma membrane and opening out to discharge their contents, a process known as *exocytosis*. This release process is Ca^{2+}-dependent. Synaptic vesicles that have released their contents are recovered by the reverse process, known as *endocytosis*, pulled back into the terminal and recycled. The process is similar to and is possibly an evolutionary adaptation of the general process of cell secretion, with the important difference that whereas in normal secretion vesicles are used only once before being returned to the Golgi region of the cell body for reprocessing, synaptic vesicles are recovered, refilled, and reused.

The synthesis, storage, and release of transmitter demands considerable amounts of metabolic energy so it is not surprising that presynaptic nerve terminals contain local concentrations of the organelles responsible for cellu-

Figure 7. An axodendritic cortical synapse in situ (A) and a synaptosome derived from it (B) with the aid of an homogenizer (C)

A) Cortical synapse, three synapses are outlined: a) Presynaptic terminal bulb filled with synaptic vesicles and containing mitochondria and presynaptic dense projections; b) Dendritic spine with dense postsynaptic membrane and spine apparatus; Bar in lower left-hand corner represents 0.2 µm

B) Synaptosome: c) Postsynaptic membrane still adhering to the synaptosome; Bar in lower left-hand corner represents 0.2 µm

C) Homogenizer: d) Precision-bore glass tube (mortar); e) Rotating (900 rpm) plastic pestle, tissue suspended in iso-osmotic sucrose is forced between the pestle and mortar.

lar respiration and energy production, the *mitochondria*.

The postsynaptic region of the synapse sometimes shows specializations and provides a basis for classification. Thus, in the CNS a broad distinction can be made between *axoaxonic*, *axosomatic*, and *axodendritic* synapses according as to whether the presynaptic axonal termination is made with another nerve terminal, or the cell body or dendrites of the target cell, respectively. Axodendritic synapses are often made, not directly onto the dendrite, but onto a small projection from it called a spine (Fig. 7 A). The numerous spines on dendrites of large neurons of the CNS give them a "furry" appearance in silver staining (Fig. 1 A). There is some evidence that spines increase in size with continued use of the synapse concerned. This is one of the few morphological indications of the elusive synaptic remodeling that must accompany learning and memory.

4.2. Neurophysiology

Physiological techniques have the advantage that they can be applied to the intact animal or to surviving tissue so that the results are often easier to interpret than those obtained by other methods. Against this, physiological methods often leave us with a model of a vital process in which basic mechanisms are concealed within "black boxes".

The simplest preparations for the physiological investigation of the nervous system are single neurons or single synapses. Conduction down axons or transmission across synapses is detected by recording the transient electrical signals that accompany nerve impulses with fine microelectrodes coupled to amplifiers and oscilloscopes (Fig. 8 A). Use is often made of invertebrate preparations (e.g., the giant axon and giant synapse of the squid) that can be penetrated by the microelectrode. Such intracellular recordings, in which the potential across the cell membrane is measured, reveal that in neurons, as in other cells, a resting potential exists across the membrane whose magnitude can be inferred from the difference in K^+ concentrations (strictly, activities) between the inside and outside of the cell. Living cells generally maintain K^+ concentrations in their cytoplasm higher, and Na^+ concentrations lower than those of the extracellular medium. If the membrane is permeable solely to potassium ions, a potential E_m arises across the membrane of a magnitude close to that predicted by the Nernst equation

$$E_m = \frac{RT}{F} \ln \frac{[K_0^+]}{[K_i^+]} = 58 \log_{10} \frac{[K_0^+]}{[K_i^+]} \text{ at } 20\,^\circ\text{C}$$

where R is the gas constant, T the absolute temperature, F the Faraday constant, and $[K_0^+]$ and $[K_i^+]$ the outside and inside K^+ concentrations respectively; under normal resting conditions E_m is close to -75 mV. When a nerve impulse is generated, usually by stimulating the nerve cell electrically, an intracellular electrode registers a transient reversal of the membrane potential due to a short-lasting rise in permeability to Na^+. The Na^+ potential temporarily superimposes itself on the resting potential. Recovery ensues as the Na^+ channel closes and is assisted by a transient increase in K^+ permeability.

Figure 8. Types of glass electrodes
A) Simple microelectrode for intracellular recording; B) Patch-clamp electrode; C) Multibarrelled electrode (not to scale)

Permeability to ions is brought about by selective, voltage-sensitive ion channels embedded in the membrane. These are complex membrane-spanning proteins whose structure is now known as a result of their isolation and sequencing by the complementary DNA (cDNA) technique. However the fine conformational changes that accompany the opening and closing of the channels are not yet fully understood. Local anesthetics (e.g., cocaine) act by blocking influx of Na^+ (→ Local Anesthetics).

The opening and closing of single ion channels in the membrane can be detected by means

of "patch-clamp" electrodes (Fig. 8 B). These are polished glass electrodes with a small hole in the tip onto which a patch of cell membrane is drawn by suction. A good seal is essential for the detection of the very small electrical signals caused by the spontaneous opening and closing of single ion channels and requires a "clean" membrane. The method works well with certain isolated cell preparations and a large range of ion channels, some of them "ligand-gated" (i.e., opened by specific substances such as transmitters interacting chemically with the channel protein), have been detected and studied.

At the synapse, the signal is transformed from an electrical to a chemical one by the inflow of Ca^{2+} ions through voltage-sensitive calcium channels that are activated by the arrival of a nerve impulse. This causes the exocytosis of numerous vesicles and the release of transmitter, which rapidly diffuses across the 25 to 100-nm synaptic gap and triggers a response in the postsynaptic target cell. Responses are of several kinds but are easiest to detect when they involve the opening of transmitter-controlled ion channels in the postsynaptic membrane and the generation of an excitatory postsynaptic potential (EPSP). This in turn, if large enough, will generate a propagated impulse in the postsynaptic cell. In muscle cells, this propagated impulse is accompanied by muscle contraction.

Analysis of the magnitude of EPSPs reveals them to be made up of subunits or quanta, whose release is synchronized by the arrival of the nerve impulse [9]. The morphological counterparts of these quanta are the synaptic vesicles, the exocytosis of a single vesicle generating a single quantum.

An example of a more complex electrophysiological investigation is the use of the multibarrelled electrode (Fig. 8 C) which may be inserted into the CNS with its tip in proximity to a nerve cell. One "barrel" of the electrode records the response of the cell to chemical substances or drugs released from other barrels by iontophoresis. A complete pharmacological experiment can be performed in this way on a single central neuron. This technique has been important in revealing the responses of central neurons to drugs and putative transmitters.

Intracellular recordings from neurons in specialized areas of the CNS, often using indwelling electrodes in animals free to move, has led to the discovery that neurons are involved in a hierarchy of organization and has given important insights into the functioning of the CNS. This is a complex subject which can only be touched upon in this article. To give one striking example: certain neurons in the striatal vocal center of birds respond when the bird hears the call of its own species but not when it hears those of other species or sounds in general. Such cells are at the apex of a complex process of neural analysis.

Physiological methods have also revealed the existence of conditioned reflexes. The pioneer in this field was I. P. Pavlov (1849 – 1936) who noted that dogs who regularly heard a bell each time they were fed quickly salivated at the sound of the bell alone, in the absence of the sight or smell of food. This approach with its many variants and model systems, ranging from invertebrates to primates, has shed light on such important higher neural functions as learning and memory.

Perhaps the chief failure of neurophysiology is to provide a convincing theory of how the "logic units"–repetitive groups of neurons whose connections and individual properties are known in some detail– combine to achieve the pattern recognition, control of skilled movements, or other quasi-computer-controlled activities of the nervous system. This may well have to await a better understanding of the properties of networks of interacting components.

4.3. Neurobiochemistry (Neurochemistry)

The biochemical investigation of the nervous system has given rise to the subdiscipline of neurobiochemistry (neurochemistry) which includes the investigation of the nervous system by cell- and molecular-biological, and molecular genetical methods. Such methods may reveal little about the way the nervous system functions as a whole, but they can help in prying open the physiologists' "black boxes" to reveal what is going on inside. They are also of great importance in understanding long-term phenomena such as development and aging, and the interaction between the nervous system and the immune and hormonal control systems.

Such investigations often begin by the application of *tissue fractionation techniques*. These involve dispersion of the tissue and fractionation by centrifugal density gradient separation or particle exclusion chromatography. The technique was originally developed for use with tissues with a relatively homogeneous and easily disrupted cellular structure like liver, but in the early 1960s the author of this article and his colleagues pioneered their application to the much more complex mammalian brain [10]. The application of mild liquid shear in a "homogenizer" (Fig. 7 C) breaks open nerve and glial cells, fragments axons and dendrites, and "pinches off" the club-like presynaptic nerve terminals to form sealed structures called *synaptosomes* (Fig. 7 B). A combination of moving-boundary (differential) centrifugation, in which particulate structures are sedimented in progressively more intense centrifugal fields, and density gradient centrifugation, in which such structures are centrifuged until they reach a region of the gradient whose density matches their own, allows synaptosomes to be separated from other organelles and cell fragments such as nuclei, mitochondria, myelin fragments, and vesiculated membrane fragments (microsomes) derived from external and internal cell membranes.

Synaptosomes are sealed structures and conserve to a remarkable degree the properties of the synapse. Morphologically, they retain the characteristic structure of the presynaptic nerve terminal, with its small mitochondria and synaptic vesicles (Fig. 7 B). Physiologically, they are capable of respiring and generating ATP when incubated in a balanced saline medium containing an energy-yielding substrate such as glucose. Such metabolizing synaptosomes take up glucose, transmitters or their precursors by carrier-mediated mechanisms and provide a convenient in vitro system on which to test the action of drugs on such processes. Anorexiants are an example of a class of drugs which may act by controlling monoamine uptake (→ Anti-Obecity Drugs). Synaptosomes also release transmitter in a Ca^{2+}-dependent manner when depolarized with high concentrations of K^+ or Na^+ plus veratridine, a drug that depolarizes by opening up Na^+ channels. Fluorescent probes that report membrane potentials confirm that metabolizing synaptosomes possess a resting membrane potential of the same magnitude as that of intact neurons and analysis of their internal K^+ and Na^+ concentrations shows that they are able to maintain ionic gradients of the requisite magnitude.

Synaptosomes disrupted by osmotic shock release their contents: density gradient separation of these yields fractions of presynaptic terminal cytosol, synaptic vesicles, presynaptic plasma membranes and intraterminal mitochondria for further biochemical analysis. Transmitters are specifically associated with the synaptic vesicles, in the case of acetylcholine, in the amount required by the vesicle theory [11].

Milder disruptive procedures, involving teasing tissue through stainless steel or nylon sieves of decreasing mesh size, yield intact cell bodies. Astrocytes, oligodendrocytes and neurons can be isolated in this way, usually after a short further fractionation of the initial cell dispersion. If cells are prepared from embryonic or neonatal brain, they are often viable in tissue culture.

One class of neuronal cytoplasmic constituents of great importance is comprised by the mRNAs (Section 4.1) that code for the numerous proteins needed for neuronal structure and function. In general, neurons are rich in mRNA, because their cell bodies have to maintain an enormously expanded peripheral cytoplasm enclosed within the dendrites and axon (Section 5.4). A mRNA coding for a functional protein (e.g., an ion channel or receptor) may be tested for activity by transfecting a frog oocyte (egg cell) with it. The transfected oocyte is not only able to synthesize the appropriate protein, it can effect any necessary posttranslational modification and the required protein is then expresssed on the oocyte's cell membrane. The protein can be sequenced by making cDNA (Section 4.1) to the neuron's mRNA, inserting this into the DNA of the bacterium *Escherichia coli* and detecting bacterial clones bearing the appropriate cDNA sequence either by hybridization with a synthetic oligonucleotide whose sequence is based on a partial sequence of the protein in question or by immunochemical means. In the latter procedure, the cDNA is inserted into the host cell along with an "expression vector" which directs the synthesis of protein according to the code supplied by the cDNA insert.

Although cellular or subcellular preparations are preferred for neurochemical studies, a variety of more integrated preparations are available.

Tissue slices, thin enough (0.3 – 0.5 mm) to allow for adequate oxygenation and rapid penetration and diffusion of metabolites, are viable for several hours in a suitable oxygenated medium and permit metabolic processes, electrophysiological recordings, and drug responses to be studied. In the form of a *sterile explant*, tissues and cells may survive for days or weeks; neurites may grow out from the neurons present and form synapses with neighboring cells, thus providing a test system for detecting endogenous *neuronotrophic factors* released by glial or target cells that are essential for neuronal survival and differentiation.

An even higher level of organization is made experimentally accessible by *perfusion of the brain*. "Push – pull cannulae" allow perfusion of a restricted brain region by injecting fluid through the annular space between concentric cannulae and withdrawing it through the inner cannula, or perfusion of portions of the hollow spaces (ventricles) within the brain. Such cannulae have proved useful in detecting transmitter release or investigating the metabolism of transmitter precursors associated with specific brain subsystems. In a later variant (microdiffusion) the cannula ends in a semipermeable membrane.

The highest organizational level of all is reached by the introduction of metabolites or markers into the blood just before it enters the brain. Neural activity in response to stimuli causes local increases in blood circulation or metabolism which can be followed by the local accumulation of label. In an earlier form of the technique, radioactive deoxyglucose was used; the brains were fixed, sectioned, and subjected to autoradiography to determine the local accumulation of the label. In *positron-emission tomography* (PET), which can be applied to humans, the label is a short-lived positron – emitting radionuclide (^{15}O, ^{13}N, ^{11}C, or ^{18}F) generated in a nearby cyclotron. An array of radiation detectors picks up the γ-rays generated by the annihilation of the positrons by electrons in the environment, and computer tomography is used to convert the response of the array to an image of the positron distribution in the tissue in real time. Cerebral blood flow may be detected with $[^{15}O]CO_2$ or $[^{15}O]H_2O$ and the distribution of a variety of metabolites and drugs may also be studied. In spite of the huge capital and running costs of the equipment, this method is now widely used in neuropharmacological research and in clinical investigation. The dynamic character of the results obtained with living patients gives the method a unique power.

Another noninvasive technique, less well developed but of great potential, is *magnetic resonance imaging* (MRI). In its simplest form nuclear magnetic resonance (NMR) signals from hydrogen atoms are transformed by computer tomography to provide an image of the distribution of the resonating atom in any required plane. Most of the signals come from the hydrogen of water, but the image of the tissue so obtained is superior in contrast and resolving power to that obtained by X-ray computed tomography (CT); brain cancers, plaques, vascular damage and other brain abnormalities can be detected. In principle, MRI could also be used to detect the compartmentation of metabolites and the kinetics of their reactions, changes in intracellular pH and the distribution of drugs in small tissue volumes using ^{31}P, ^{13}C, or fluorine labeling.

In spite of the advantages of these new noninvasive techniques, the picture of the nervous system furnished by neurochemistry remains stubbornly molecular. It has much to tell us about development, aging and the function and modus operandi of the units which make up the system but does not reveal how it works as a whole.

4.4. Neuropharmacology

The ideas and concepts of pharmacology, especially that of specific tissue receptors for drugs and toxins, have greatly influenced the understanding of the nervous system. Transmitters and other endogenous neuroactive substances may be described as *autopharmacological agents*. Until chemical or immunochemical methods are devised they must be estimated by *bioassays*, in which the response of the assay system – often the contraction of a muscle registered by a recorder coupled to a strain gauge – is matched by a "standard". The standard may be the endogenous substance itself (if known), a stable preparation of the endogenous substance whose activity is expressed in arbitrary units, or another, known substance with pharmacologically similar or identical properties. Further characterization may involve parallel assays in which comparisons are made between unknown and

standard in two or more bioassay systems with different ligand specificities. Bioassay–although sensitive, rapid, and accurate in experienced hands and requiring inexpensive equipment–has largely been superseded by other methods such as fluorimetry, gas chromatography, high performance liquid chromatography (HPLC), or radioimmunoassay.

The existence of a drug with a powerful action on the nervous system prompts the search for a receptor. This is greatly helped by the use of radiolabeled drugs and a theoretical analysis of the binding data which leads to the calculation of affinity constants and other parameters. At this stage a crude membrane preparation may be all that is required as a source of receptor. The uncritical application of the technique has, however, led to the pejorative description "grind and bind" research.

If well-founded evidence for a specific receptor is obtained, its presence suggests the possible existence of endogenous ligands. Thus, when morphine-specific receptors were found in the brain, a search was instituted for endogenous morphine-like substances (opioids). Some 14 such substances are now known and include short-chain peptides (the *enkephalins*) and the longer chain *endorphins*, all of which contain the common sequences tyr-gly-gly-phe-leu or tyr-gly-gly-phe-met. Centrally acting analgesics and antitussives are among those pharmaceuticals interacting with the brain opioid system (→ Analgesics and Antipyretics ; → Cough Remedies).

Specificity studies of receptors for endogenous ligands, using synthetic analogues, often enable apparently identical receptors to be resolved into a number of subtypes (Chap. 5).

Drugs and toxins often have profound effects on the nervous system in extremely low doses. Thus as little as 10 µg of the hallucinogen lysergic acid diethylamide (LSD) causes disturbance of consciousness in humans, while 1 ng doses of botulinum toxin evoke toxic symptoms. Such extreme sensitivity to drugs illustrates the importance of chemical processes in the working of the nervous system.

5. Synaptic Transmission

5.1. Historical Background

The preceding chapters have shown that the synapse is a specialized region of contact and chemical secretion between the presynaptic neuron and its target cell (neuron, muscle, or gland cell), that transmitters are stored in the synaptic vesicles of the nerve terminals or varicosities, that release is brought about by vesicle exocytosis, that vesicles can be recovered and reutilized, that release is quantized, and that the response of the postsynaptic membrane to transmitter release is frequently the opening of a ligand-gated ion channel in the postsynaptic membrane induced by the transient binding of the transmitter to the channel at a specialized receptor site. Estimates of the number of different transmitters vary, but may well exceed 20.

The observation by C. Bernard (1813–1878) that the South American arrow poison, curare, blocked neuromuscular transmission without affecting the excitability of either the nerve or the muscle, showed that excitation changes its character at the junction between nerve and muscle and becomes particularly sensitive to chemical blockade. It did not however immediately lead to the concept of chemical transmission at synapses: at the turn of this century, resemblances were seen on the one hand between the physiological effects of adrenaline and stimulation of sympathetic nerves and on the other between the effects of muscarine and stimulation of the parasympathetic system. This led to the suggestion that adrenaline, or something similar, mediated sympathetic stimulation and muscarine, or an endogenous analogue, mediated parasympathetic stimulation. Another alkaloid, nicotine, was found first to stimulate and then to block synaptic transmission through autonomic ganglia and this property enabled the anatomy of the autonomic system (Section 3.1 and Fig. 4) to be worked out. U. S. von Euler (1905–1983) discovered that the transmitter at most sympathetic nerve terminals is noradrenaline rather than adrenaline and the work of O. Loewi (1873–1961) and H. H. Dale (1875–1968) showed that the transmitter at autonomic ganglia, most parasympathetic nerve endings, and at neuromuscular junctions is acetylcholine. Dale coined the convenient–if not quite accurate–terms adrenergic and cholinergic to describe the

two types of synapse and this terminology has been extended subsequently to cover other transmitters.

The fact that muscarine and nicotine do not have identical actions on cholinergic synapses, indicates that the acetylcholine receptors in the target cells have markedly different *chemical specificities* as well as differing physiological roles. This was the first example of an important development in pharmacology: the classification of receptors having a common endogenous ligand by means of agonists or antagonists of known but different structures. Thus acetylcholine receptors may be classified as muscarinic (these are found at postganglionic parasympathetic nerve terminals and in the CNS) and nicotinic (found in autonomic ganglia, at the neuromuscular junction, and also in the CNS). That there is more than one subtype of nicotinic receptor is shown by the fact that the muscular relaxant decamethonium is an excellent blocker of neuromuscular transmission, whereas hexamethonium, not very effective at this synapse, is much more so in autonomic ganglia. There are at least two subtypes of muscarinic receptor (designated M_1 and M_2) and at least four types of adrenergic receptors (α_1, α_2, β_1, and β_2). Multiple types of glutamate (probably three) and γ-aminobutyrate (at least two, $GABA_A$ and $GABA_B$) are also known.

The isolation and sequencing of receptors from different parts of the nervous system has fully confirmed the existence of subtypes. In situ hybridization shows that these subtypes are not mingled together indiscriminately but may be specific for particular classes of neuron. This opens up the possibility of very specific drug targeting if variants can be synthesized which specifically recognize the subtypes thus far known only from their molecular composition.

5.2. Survey of Transmitters

5.2.1. Low Molecular Mass Transmitters

The first transmitters to be identified were the low molecular mass compounds noradrenaline and acetylcholine.

Noradrenaline
[*51-41-2*]

Acetylcholine
[*51-84-3*]

Others followed: dopamine, 5-hydroxytryptamine (5-HT, also known as serotonin), glutamate, γ-aminobutyrate (GABA), glycine, and, less certainly, histamine, aspartate, and taurine. Such transmitters are often nowadays referred to as "classical" transmitters, in contradistinction to the neuropeptides (Section 5.2.2).

Dopamine
[*51-61-6*]

5-Hydroxytryptamine
[*50-67-9*]

Glutamate
[*56-86-0*]

γ-Aminobutyrate (GABA)
[*56-12-2*]

Glycine
[*56-40-6*]

Histamine
[*51-45-6*]

Aspartate
[*56-84-8*]

Taurine
[*107-35-7*]

The classical transmitters are usually synthesized in the nerve terminal cytoplasm and are stored in synaptic vesicles. Uptake by synaptic vesicles is carrier mediated and driven by an inwardly directed proton gradient across the vesicle membrane. Release is via Ca^{2+}-activated exocytosis of synaptic vesicles; the vesicles are recovered and refilled with the locally synthesized or recovered transmitter, a process known as vesicle recycling. Transmitter release is thus not immediately dependent on axonal transport (Section 5.4). The released transmitter is salvaged by a high affinity, carrier-mediated uptake system in the presynaptic terminal, either as such or in the form of its hydrolysis products. Thus acetylcholine is hydrolyzed to choline and acetate by the enzyme acetylcholinesterase, present in high concentration in the synaptic

cleft; both hydrolysis products are taken up and resynthesized to acetylcholine.

The hydrolysis of acetylcholine is also an inactivating mechanism, since choline has only one ten-thousandth of the activity of acetylcholine on acetylcholine receptors and acetate is not a ligand for such receptors. Inactivation mechanisms involving oxidation, methylation, and other reactions also exist for other transmitters, but these usually come into play only when the concentration of transmitter in the synaptic cleft is very high; the usual form of inactivation is the presynaptic uptake of the transmitter. This applies to the catecholamines, 5-HT, and the amino acids, but not histamine. In the case of the amino acids, glial cells may also play a part in the uptake process.

Acetylcholine and noradrenaline are transmitters at numerous peripheral and central synapses. Glutamate is an excitatory transmitter widely distributed in the CNS of mammals; in many invertebrates (arthropods, cephalopods) it replaces acetylcholine as the excitatory transmitter at the neuromuscular junction. Dopamine and 5-HT are excitatory transmitters in the mammalian central nervous system; GABA and glycine are inhibitory transmitters in the brain and spinal cord, respectively. In arthropods inhibition is brought about not centrally but by specific inhibitory endings in the muscles where GABA is a transmitter; indeed, GABA was first discovered by using the inhibitory nerve to the stretch receptor of the crayfish as an assay system.

Inhibition is a widespread and important phenomenon in the CNS. Without it, the smooth relaxation of an antagonist muscle when an agonist contracts would be impossible, and painful cramps would accompany any movement. Thoughts and behavior would become wild and disordered. Inhibitory synaptic transmission involves the release of transmitter, the transmitter opening chloride channels instead of channels for sodium and potassium; chloride ions move into and transiently *hyperpolarize* the postsynaptic neuron. Hyperpolarization raises or stabilizes the neuron's resting potential, thereby partially or completely neutralizing excitatory postsynaptic potentials and preventing them from achieving the membrane depolarization which would trigger off a propagated impulse. Epilepsy has been defined as "a disorder of brain function characterized by the episodic recurrence of paroxysmal neurological or behavioral manifestations caused by abnormal synchronous and excessive discharges of large groups of neurons" [1]. The cause is obscure but may be related to an abnormal accumulation of the excitatory transmitter glutamate, a reduced availability of the inhibitory transmitter GABA, or an excessive accumulation of extracellular K^+ which would cause massive depolarization of neurons and extensive discharges (→ Antiepileptics). Two other classes of drugs exert a general effect on neuronal excitability in the CNS, the analeptics, which stimulate (→ Analeptics) and the sedatives (→ Sedatives) which depress it. A fourth class, the neuroleptics, which include some sedatives, seem to act primarily on D_2 dopamine receptors (Section 5.3.3).

5.2.2. Neuropeptides

The discovery of neuroactive peptides in the nervous system grew out of the discovery of peptide and protein hormones (→ Peptide and Protein Hormones). The first hormone to be discovered was secretin which is released from the intestine and evokes pancreatic secretion. Many others followed; among the most important are insulin and glucagon both of which are released from the pancreas and regulate blood sugar, but in opposite directions. The intestine continued to yield hormones, among them substance P, vasoactive intestinal polypeptide (VIP) and cholecystokinin (CK).

Another potent source of physiologically active peptides is the pituitary, or hypophysis, a gland at the base of the brain. Here are found hormones controlling diuresis and water balance (vasopressin), milk ejection (oxytocin), growth (growth hormone), reproductive function (the two gonadotropins, namely luteinizing hormone and follicle-stimulating hormone), lactation (prolactin), fat mobilization (β-lipotropin), thyroid activity (thyrotropin), and adrenal cortical activity (adrenocorticotropic hormone). These in turn are controlled by peptides located in the region at the base of the brain known as the hypothalamus. Such hormones either stimulate (releasing hormones) or inhibit (releaseinhibiting hormones) the release of pituitary hormones.

Releasing hormones for the gonadotropins, thyrotropin, adrenocorticotropic hormone, and growth hormone, and a release-inhibiting hormone for growth hormone (somatostatin) have been characterized. The hypothalamus also links up with the autonomic nervous system; thus the hypothalamic – hypophyseal axis is extremely important for central nervous control of bodily function and metabolism.

Peptides are found in bewildering variety at all levels of the phylogenetic tree down to *Hydra*, a simple animal related to the sea anemone. Some peptides have definite functions, thus one peptide in *Hydra* is essential for the differentiation of the head region and has been detected in the rat hypothalamus; another, in *Aplysia* (a sea-slug) regulates egg laying; others may act as neurotoxins. Frog skin has yielded at least a dozen peptides, many resembling those found in the mammalian hypothalamus and elsewhere.

Immunological techniques have been extremely important in studying the neuropeptides. Specific antisera or monoclonal antibodies (mABs) raised to them have enabled them to be estimated in tissues and subcellular fractions by means of *radioimmunoassay*. Such sera or antibodies have also been extensively used to localize the peptides they recognize in tissues, including nervous tissue, by applying the techniques of immunocytochemistry. Usually, the specific antiserum or mAB is applied after permeabilizing tissue sections with a detergent. After washing out unbound antibody, a second antibody, labeled with a fluorescent group and directed against the immunoglobulin fraction of the animal providing the antiserum or mAB is applied. The section is washed again and the location of the original antigen is revealed by the pattern of fluorescence observed under the microscope.

Such studies have given two remarkable results: (1) peptides including many already identified as hormones are widely but not uniformly distributed in the nervous system; and (2) the neurons staining positively for peptides often utilize low molecular mass, classical transmitters. Certain peptides tend to be associated with certain classical transmitters such as GABA, acetylcholine, and noradrenaline. Thus it has been estimated that 50 % of all central cholinergic terminals also contain VIP and that 75 % of all VIP-containing terminals are also cholinergic [12]. Although peptides (neuropeptides) are present throughout the neuron, they tend to be highly concentrated in the terminals and can often only be identified in cell bodies by using colchicine to block axonal transport (Section 5.4), the process whereby substances or organelles synthesized in the neuronal cell body are conveyed to the terminal.

It thus seems reasonable to conclude that neurons primarily utilize neuropeptides as transmitters. When a classical transmitter coexists with the neuropeptide, the latter may be regarded as a cotransmitter. Neuropeptides are indeed released from nerve terminals on stimulation in a Ca^{2+}-dependent manner and can induce or modify electrical responses in postsynaptic membranes. A good example is substance P which is released on stimulation of afferent neurons entering the spinal cord of the type mediating pain. Neuropeptides differ considerably from classical transmitters in the dynamics of their synthesis, storage, and release [13, 14]. Thus they are not stored in synaptic vesicles as the classical transmitters are but in larger vesicles, which sometimes have electron-dense cores (i.e., have black-looking cores in electron micrographs). They cannot be synthesized in the nerve terminals or salvaged after release so there is no recycling vesicular pool. This means that release is completely dependent on axonal transport.

These differences in intracellular dynamics suggest that the pattern of release of neuropeptide cotransmitters reflects the past intensity and duration of stimulation of the neurons containing them. This could result in a subtle regulation of the rate of synthesis and pattern of release of the classical cotransmitter, especially if the neuropeptide combines with receptors to release "second messengers" (Section 5.3.2) able to regulate intracellular transmitter metabolism.

Neuropeptides are rarely if ever synthesized as such; they are the products of the posttranslational modification of much larger molecules, known as propeptides (prohormones) or prepropeptides (preprohormones). These contain the sequences of neuroactive peptides as segments separated by lysine – lysine or lysine – arginine, points at which the propeptide is easily cleaved by proteolytic enzymes. Thus the hypophyseal hormones adrenocorticotropic hormone, γ-melanotropin and β-lipotropin are synthesized as parts of a single much larger prohormone; adrenocorticotropic hormone itself con-

tains the sequence of α-melanotropin while β-lipotropin breaks down to yield the opioid peptide β-endorphin and γ-lipotropin; the latter in turn yields β-melanotropin.

The discovery of the neuropeptides has opened up a baffling yet exciting new era in neurobiological research. In many cases the function of these peptides in the brain is not known; some may act as transmitters, but others may have a modulating role or link the nervous system with the autonomic system, the immune system or tissue repair after injury. The implications for neuropharmacology are also immense, if stable analogues with antagonistic or agonist properties can be successfully prepared.

5.2.3. Evolutionary Significance of the Two Types of Transmitter

The low molecular mass transmitters are not found in the simplest living organisms that possess nervous systems; thus acetylcholine is not found in coelenterates and first appears in the echinoderms and platyhelminths. Their appearance may coincide with an evolutionary demand for fast, sustained movement. It is probable that neuropeptides were the first transmitters and that chemical transmission is an adaptation of humoral secretion. Neuropeptide secretion is dependent on de novo synthesis and axonal transport, these processes are wasteful and relatively inefficient especially as the size of organisms increased and axons grew longer, separating the sites of synthesis and release by ever greater distances.

Chemical transmission, especially when speeded up by recycling, remained however an attractive mechanism. The store of transmitter in the presynaptic terminal guarantees unidirectional synaptic transmission–an essential prerequisite for the orderly processing of information. If an antidromic impulse (i.e., one travelling in the reverse direction) should arise in an axon, it would be unable to effect reversed transmission due to lack of a store of transmitter in the neuronal cell body or dendrites.

The existence of more than one transmitter and specific receptors for them may be a device to suppress "cross-talk" between interdigitated but functionally distinct systems. The retention of neuropeptides as transmitters or cotransmitters alongside the classical transmitters is harder to explain. Some may represent the vestigial survival of phylogenetically old transmitters which evolutionary pressures were not strong enough to eliminate. Others clearly retain a transmitter function in circuits where short synaptic delays and continuous action may not be so important, as in pain afferents. Yet others have a regulating role or have important hormonal functions linking the nervous system to other body systems.

All chemical synapses– even those using fast-tacting, easily mobilized transmitters–impose a short delay of not less than 0.5 – 1 msec. It is significant that where fast action has evolutionary survival value (e.g., the escape reactions of decapods), chemical transmission has been abandoned for the even faster electrical (electrotonic) transmission in the corresponding neuronal circuits. Electrical transmission is also less temperature dependent than chemical transmission, which may explain why electrotonic synapses are more frequently encountered in cold-blooded animals. Such synapses show apposition of pre- and postsynaptic membranes and are devoid of synaptic vesicles.

5.3. Transmitter Action

5.3.1. Fast Ionotropic Action

The term ionotropic action denotes the action of transmitters which operate by opening channels in the postsynaptic membrane. Such action is swift and terminated by spontaneous closing of the channel and the inactivation of the transmitter by hydrolysis or reuptake.

Excitatory Ionotropic Action . Both acetylcholine (when acting on nicotinic receptors) and glutamate are examples of fast-acting excitatory transmitters. The nicotinic acetylcholine receptor (nAChR) was first isolated in a pure form from an exceptionally rich source: the electric organ of the electric ray, *Torpedo*. Such organs consist of a honeycomb array of columns of flattened cells, called electrocytes, which are embryologically derived from muscle with loss of the contractile machinery; each electrocyte is 80 % covered on its under surface with cholinergic nerve terminals. Electric organ contains

weight for weight, 500 – 1000 times more synaptic material and nAChR than muscle and isolation of the latter becomes a feasible proposition.

Isolation of the receptor was made possible by the discovery that one of the main proteins of cobra venom is a powerful neuromuscular blocking agent and has a high affinity for the receptor. The receptor was solubilized in detergent and adsorbed onto columns of immobilized venom; after washing the column, the receptor could be eluted in concentrated form. It consists of four peptides of molecular masses 40 (α), 50 (β), 60 (γ), and 65 (δ) kDa; the complete receptor is a complex of all four in which the α-peptide is repeated twice. In negative staining the complex appears as a pentagon with a central hole presumed to be the ion channel.

All four peptides have been sequenced [15]: each contains four hydrophobic transmembrane segments and the complete molecule is an assembly of 20 such segments forming an ionic channel through the membrane. When two molecules of acetylcholine bind to the two α-subunits an allosteric change takes place and the channel opens. The channel opening time varies with the ligand. Each package (quantum) of transmitter opens 5000 – 6000 such channels and generates a transient change of about 0.2 mV in the resting membrane potential of the postsynaptic membrane. The *Torpedo* electrocyte is not electrically excitable and cannot conduct an impulse but in an excitable nerve or muscle cell, the synchronized release of several hundred such quanta will generate a postsynaptic potential change sufficient to initiate a conducted response. Reversible neuromuscular blocking agents (muscular relaxants) usually contain two quaternary nitrogen atoms separated by a bridge of carbon atoms instead of one as in acetylcholine. Such compounds block by straddling the two α-subunits of the receptor. One such muscular relaxant, succinylcholine, is readily hydrolyzed and provides a transient, easily controlled block very useful in abdominal surgery. By contrast the snake toxins work by blocking the ion channel directly.

The characterization of the nAChR has been followed by that of the glutamate receptor, which operates on similar lines.

Inhibitory Ionotropic Action. The nature of spinal inhibition was worked out by J.C. Eccles (b. 1903) using microelectrodes inserted into motor neurons and the reflex activation of inhibitory interneurons (Section 3.2.1) [2]. His observation that minute amounts of a chemical substance, strychnine, could block inhibition convinced him that an inhibitory chemical transmitter, subsequently identified as glycine, must be involved. To identify the ligand-gated ionic channel involved, different ions were injected into motor neurons and the effect on the inhibitory (hyperpolarizing) postsynaptic potential (IPSP) generated by the reflexly activated interneuron was observed. The IPSP could be abolished and then converted to a depolarizing potential by increasing the internal Cl^- concentration of the cell, showing that the ionic channel opened by the transmitter is a Cl^- channel. Hydrated univalent anions smaller or only a little larger than Cl^- also reduce the IPSP and are thus also able to pass through the Cl^- channel; other ions (e.g. organic anions, di- or trivalent inorganic anions) are ineffective.

The high affinity of strychnine for the glycine receptor has enabled the latter to be isolated and sequenced using affinity chromatography on immobilized strychnine.

In the brain and the dorsal horn of the spinal cord, GABA (not glycine) is the inhibitory transmitter. It acts in a similar way to glycine but its receptor has a different pharmacological specificity: it is blocked by picrotoxin and bicuculline (ineffective at glycine receptors) but not strychnine. Presynaptic inhibition (i.e., inhibition exerted on excitatory presynaptic nerve terminals by inhibitory synapses present on them) is also mediated by this transmitter.

5.3.2. Slow Metabolotropic Action

Acetylcholine at muscarinic receptor sites, the monoamine transmitters (noradrenaline, dopamine, 5-HT, histamine), and probably some neuropeptides do not operate directly through ligand-gated ion channels but via *second messengers*. These messengers are intracellular components capable of regulating a variety of intracellular functions (including that of ion channels) which in turn are mobilized by binding the transmitter (or an agonist analogue) to its receptor. An intricate series of reactions has been implicated (Fig. 9). The basic features are:

Figure 9. Scheme showing sequence of events regulated by metabolotropic receptor (R)
Allosteric changes are shown schematically by different geometric figures.
1) Agonist A combines with complex of R, G-protein (G) and adenylate (guanidylate) cyclase (C).
2) The ligand-induced conformational change in R communicates itself to G which binds GTP and through G to C which converts ATP (GTP) to cyclic AMP (cyclic GMP).
3) Cyclic AMP (cyclic GMP) activates a protein kinase which regulates functional proteins by phosphorylating them.

1) the identification of a family of G (or N) proteins which link the receptor to adenylate (or guanidylate) cyclase,
2) the regulation of protein kinases by the cyclic adenosine 3′,5′-monophosphate (cAMP) or cyclic guanosine 3′,5′-monophosphate (cGMP)
3) the regulation of functional proteins by phosphorylation catalyzed by such kinases.

Most receptor-regulated cyclases are adenylate cyclases but those regulated by H_1 (histamine receptor) and mAChR (acetylcholine receptor) are guanidylate cyclases. In some cases the functional proteins so regulated are ion channels. Thus an important effect of the activation of α_2 receptors by noradrenaline is a long-lasting inhibition achieved by an increase in K^+ conductance following channel phosphorylation. In other cases, proteins controlling gene expression may be so regulated. A phospholipase C capable of generating triphosphoinositide and diacylglycerol from a membrane phospholipid is yet another protein to be thus regulated. Both of these substances can release Ca^{2+} from intracellular membranes. The Ca^{2+} ions can react with another protein calmodulin to activate another functionally important class of protein kinases. Calcium antagonists are used therapeutically in coronary heart disease, arrhythmia, and hypertension (→ Calcium Antagonists). However, in many cases the link between protein phosphokinase activity induced by the second messenger–cAMP, cGMP–or Ca^{2+} and the physiological response has yet to be worked out.

The involvement of so many allosteric and enzymic steps may explain the relatively slow onset and long duration of such responses. This justifies the classification of these transmitter actions as metabolotropic.

5.3.3. Receptors of Importance in Drug Action

Drugs may act on receptors as *agonists* (mimetics) that produce the same action as the transmitter, or as *antagonists* (lytics, blockers, blocking agents). Several examples have already been given, notably the neuromuscular blocking agents (→ Skeletal Muscle Relaxants) which act by blocking nicotinic acetylcholine receptors in muscle subtypes (Section 5.3.1). The receptors for glutamate, GABA, noradrenaline, and dopamine are also important targets for drug ac-

tion and pharmacological analysis has revealed many subtypes.

Many clinically important drugs are used to regulate the autonomic nervous system by acting as either agonists or antagonists at the acetylcholine or noradrenaline receptors in smooth and cardiac muscle or glands. The reader is referred to other articles, for example → Antiarrhythmic Drugs, → Antiasthmatic Agents, → Antihypotensives, → Antihypertensives, → Cardiac Glycosides and Synthetic Cardiotonic Drugs, → Coronary Therapeutics, → Parasympatholytics and Parasympathomimetics, → Spasmolytics, → Sympatholytics and Sympathomimetics. One of the most widely used class of such drugs are the adrenergic β-blockers (→ β-Receptor Blocking Agents) such as propanolol which reduce blood pressure (→ Antihypertensives, → Coronary Therapeutics) and heart rate by blocking adrenergic vasoconstrictor and cardioaccelerator receptors. β-Blockers do however gain entrance to the CNS and produce depression apparently by blocking adrenergic pathways in the limbic system. By contrast, iproniazid and other monamine oxidase inhibitors, raise the intracellular concentration of noradrenaline and are antidepressive. This strongly suggests that depression involves a disturbance in CNS (possibly limbic) function mediated by adrenergic neurons, which could result either from a failure to synthesize enough noradrenaline or from a desensitization of noradrenergic receptors.

Dopaminergic transmission though not widespread is also of critical importance in the CNS. Dopaminergic cell bodies are present in the substantia nigra, a nucleus of dark hue between the hypothalamus and thalamus (Fig. 5 C) and project to the caudate nucleus (Fig. 5 B). In Parkinson's disease these neurons lose their ability to produce enough dopamine. Administration of a precursor, L-dopa, or of dopamine agonists is therapeutic (→ Parkinsonism Treatment). Conversely, agents which displace dopamine, e.g., the neurotoxin *N*-methylphenyltetrahydropyridine, induce Parkinsonian symptoms.

Dopamine pathways appear to be affected in schizophrenia. All three main classes of neuroleptic (antipsychotic) drugs, phenothiazines, butyrophenones, and thioxanthenes (→ Phenothiazine and Derivatives, → Psychopharmacological Agents), have side effects indicating the involvement of extrapyramidal neurons: Parkinsonian rigidity and tremor or dyskinesia (convulsive movements). D_2 receptor blockade correlates well with neuroleptic activity and one of the symptoms of schizophrenia, catatonia, may be related to Parkinson rigidity.

A third type of receptor of great importance for drug action is the $GABA_A$ receptor which is the main target for the anxiolytic and anticonvulsant benzodiazepines. These compounds bind to a receptor which allosterically modifies the GABA receptor to increase the efficacy of its activator GABA, an inhibitory transmitter. There is an excellent correlation between binding affinity and potency in animal and clinical tests.

5.4. Axonal Transport

The presynaptic nerve terminal cannot synthesize structural and functional proteins and lipoprotein membranes; it is entirely dependent on the synthetic activity of the cell body (perikaryon). The electromotor cell body has been estimated to maintain over 30 times its volume of presynaptic nerve terminal; similar figures must apply to other neurons. Most neuronal perikarya show corresponding signs of intense synthetic activity: they are rich in polysomes (collections of ribosomes synthesizing proteins from mRNA) and membranes, the latter often budding off synaptic vesicle-like structures.

The process whereby soluble proteins and membrane-bound organelles are conveyed from the cell body to the terminals is referred to as axonal transport. It involves more than one mechanism and rate of transport. Paradoxically, synaptic vesicles are conveyed at the fastest rate (400 mm/d), probably with the participation of microtubules (a kind of scaffolding) using a mechanism akin to muscular contraction. Larger particles (e.g., mitochondria) travel more slowly, apparently as a result of increased mechanical resistance, but soluble cytoplasmic proteins travel at the slowest rate (ca. 1 mm/d). Here the mechanism of transport is uncertain but may involve the streaming of cytoplasm within spaces between bundles of microtubules. Colchicine stops transport by causing the disassembly of microtubules.

There is also a need for retrograde transport–the conveyance of spent or worn-out organelles to the cell body for salvage–but the mechanisms involved are still unclear.

1. Introduction

Nickel, [7440-02-0], Ni, A_r 28, atomic mass 58.71, is a silver white metal with typical metallic properties. It occurs in the periodic table in the first triad of Group VIII (IUPAC Group 10), after iron and cobalt, to which it is closely related. The electronic configuration of nickel is $1s^2\ 2s^2\ 2p^6\ 3s^2\ 3p^6\ 3d^8\ 4s^2$.

Nickel occurs naturally as a mixture of five stable isotopes of mass number 58 (67.84 %), 60 (26.23 %), 61 (1.19 %), 62 (3.66 %), and 64 (1.08 %). So far seven artificial radioactive isotopes have been identified with mass numbers of 56, 57, 59, 63, 65, 66, and 67.

The great importance of nickel lies in its ability, when alloyed with other elements, to increase a metal's strength, toughness, and corrosion resistance over a wide temperature range. Nickel is essential to the iron and steel industry, and nickel-containing alloys have played a key role in the development of materials for the aerospace industry. World production of nickel increased from 20×10^3 t/a in 1920 to 750×10^3 t/a in 1976 at an average annual rate of increase of 3 %. However, no significant increase in either consumption or production occurred between 1976 and 1986, with world nickel consumption falling as low as 650 000 t/a in 1981 and 1982. The known world reserves of nickel are more than adequate to maintain this level of production for many years.

1.1. History [1-4]

It is believed that the word “Nickel” or “Kupfer Nickel” is derived from a derogatory term applied by medieval miners in Saxony to a mineral which they mistakenly believed to be a copper ore, but from which they could extract no copper. It was in fact the nickel arsenide ore niccolite (NiAs). The Saxon miners not unnaturally assumed that evil spirits, or “Old Nick” himself, were responsible for their problems.

Nickel itself was first isolated by the Swedish mineralogist AXEL CRONSTEDT in 1751, when studying agersdorffite (NiAsS) ore from Los in Sweden. Nickel's status as an independent element was proved in 1775 by BERGMANN and coworkers, but it was not until 1804 that RICHTER produced a relatively pure sample of the metal and described its essential properties.

Nickel-containing alloys were in use long before CRONSTEDT's discovery. For centuries the Chinese had been making “pai thung” or “white copper” (40 % Cu, 32 % Ni, 25 % Zn, and 3 % Fe) which resembled silver in appearance. This material appeared in Europe in small quantities in the late 1700s. Since it cost only one quarter the price of silver, the alloy had obvious commercial potential as a silver substitute. By the 1830s, copper – nickel – zinc alloys, by then known as German Silver and later as nickel-silver, were being produced commercially in both Germany and England in significant amounts. In addition to its silver color, this alloy was easy to cast and fabricate, was resistant to tarnishing, and was economical to produce. The next significant development occurred in 1857 when the United States issued a cupronickel coin containing

12 % nickel; other countries soon followed suit.

In the mid-1800s nickel was produced in small quantities from sulfide ores mined in Germany, Norway, Sweden, and Russia. Although refined metallic nickel was first produced in Germany in 1838, world production of nickel remained below 1000 t/a until 1876.

The demand for nickel increased abruptly in 1870 – 1880 when PARKES, MARBEAU, and RILEY demonstrated its use in alloy steels, as FLEITMANN succeeded in making malleable nickel, and as electrolytic nickel plating was successfully developed. The first nickel-steel armor plate was made in France in 1885 and soon afterwards in Italy, England, and the United States. In the early 1890s the adoption of nickel steels by the world's navies led to a steep rise in the demand for nickel.

In 1863, GARNIER discovered the nickel oxide ores of New Caledonia, and from 1875 this French island became the world's main producer of nickel, which position it retained until displaced by Canada in 1905. Mining of the sulfide ores of the Sudbury Basin in Ontario, Canada, started in 1886, and these ore bodies were to remain the most important source of the world's nickel supply for most of the twentieth century. Even in 1950 the Sudbury area still supplied 95 % of the nickel for the Western world. Since then Canada's preeminent position has been largely eroded, and by 1980 nickel was being mined, smelted, and refined in more than 20 countries.

Up to the end of World War I nickel was used almost exclusively for military purposes, but intensive research, between the world wars, into potential industrial uses soon led to a variety of new applications. In the 1990s there are thousands of nickel alloys in use with nickel contents ranging from 99 % in wrought nickel to as little as 1 % as hardening additives for various alloys.

1.2. Physical Properties [9-11]

The physical properties of nickel depend largely on its purity, on the physical state of the metal, and on its previous treatment. The wrought metal is highly malleable, moderately strong, tough, ductile, and highly resistant to corrosion in many media. Its good strength and ductility persist to subzero temperatures. Some important physical properties of nickel are as follows:

mp	1455 °C (1728 K)
bp	2730 °C (3003 K)
Relative density (25 °C)	8.9
Volume increase on melting	4.5 %
Heat of fusion (*mp*)	302 J/g
Heat of sublimation (25 °C)	7317 J/g
Heat of vaporization (T_{crit})	6375 J/g
Standard entropy	29.81 J/K
Thermal conductivity (0 – 100 °C)	88.5 W m^{-1} K^{-1}
Heat capacity (0 – 100 °C)	0.452 J g^{-1} K^{-1}
Electrical resistivity (20 °C)	6.9 μΩ/cm
Temperature coefficient of electrical resistivity (0 – 100 °C)	6.8×10^{-3} K^{-1}
Thermal expansion coefficient (0 – 100 °C)	13.3×10^{-6} K^{-1}
Modulus of elasticity	199.5 GPa
Brinell hardness	85

The density of molten nickel in g/cm^3 is given by

$$\varrho = \varrho_0 - 1.16\times10^{-3}(t - t_0)$$

where

$$\varrho_0 = 7.905\,,\ t_0 = 1455;$$

the surface tension in mN/m, by

$$\sigma = \sigma_0 - 0.38(t - t_0)$$

where

$$\sigma_0 = 1778\,,\ t_0 = 1455;$$

and the viscosity in mPa · s, by

$$\eta = \eta_0 \exp(E/RT)$$

where

$$\eta_0 = 0.1663\,,\ E = 855\ \mathrm{J/g}.$$

Some mechanical properties of nickel are listed in Table 1.

Table 1. Mechanical properties of nickel *

Property	Pretreatment							
	Tempered			Hot-rolled				
Temperature, °C	–200	–75	20	20	200	400	600	800
0.2 % proof stress, MPa	230	170	160	170	150	140	110	
Tensile strength, MPa	710	560	500	490	540	540	250	170
Elongation, %	54	58	48	50	50	50	60	60
Impact value (Charpy)	230	230	230					

* Nominally 99.0 % Ni.

Nickel normally forms a face-centered cubic crystal lattice, although a hexagonal modification is known, which changes to the cubic form at 250 °C. Cubic nickel is ferromagnetic below its Curie point of 357 °C, although less so than iron. The hexagonal form of nickel is not ferromagnetic.

1.3. Chemical Properties [12]

In its chemical properties nickel resembles iron and cobalt, as well as copper. The + 2 oxidation state is much the most important in nickel chemistry, although the + 3 and + 4 oxidation states are also known. The oxidation of nickel(II) salt solutions with chlorine, bromine, or persulfate in aqueous alkaline solution produces the insoluble nickel(III) oxide, β-NiO(OH). The nickel(IV) oxide $NiO_2 \cdot n\,H_2O$ is prepared by persulfate oxidation of nickel(II) hydroxide. In contrast to cobalt and iron, nickel is normally only stable in aqueous solution in the + 2 oxidation state.

Nickel(II) ions form complexes very readily. The maximum coordination number is six. The green color of most hydrated nickel(II) salts and their aqueous solutions is due to the octahedral $Ni(H_2O)_6^{2+}$ cation. The strong tendency of the nickel(II) ion to form complexes with ammonia, for example $Ni(NH_3)_6^{2+}$, or $Ni(H_2O)_2(NH_3)_4^{2+}$, is utilized in a number of extraction processes (Sections Ammonia Pressure Leaching and The Caron Process).

The most unusual property of nickel is its ability to react directly with carbon monoxide to form a binary carbonyl complex. When carbon monoxide reacts with metallic nickel at 60 °C it forms the volatile nickel tetracarbonyl, $Ni(CO)_4$ (see ⟶ Nickel Compounds). This reaction is reversible, with the carbonyl compound decomposing to carbon monoxide and nickel at higher temperatures (180 °C).

$$\mathrm{Ni} + 4\,\mathrm{CO} \underset{180\,^\circ\mathrm{C}}{\overset{60\,^\circ\mathrm{C}}{\rightleftharpoons}} \mathrm{Ni(CO)_4}$$

This reaction is the basis for the vapometallurgical refining of nickel (Section Carbonyl Refining). No other metal forms similar carbonyl compounds under such mild conditions at atmospheric pressure.

At moderate temperatures nickel has a high corrosion resistance against air, seawater, and nonoxidizing acids. Nickel is fairly electropositive with a standard electrode potential of – 0.25 V, which is similar to cobalt (– 0.28 V).

$$\mathrm{Ni} \rightarrow \mathrm{Ni^{2+}} + 2\,\mathrm{e^-}\,(E = -0.25\ \mathrm{V})$$

An outstanding property of nickel is its corrosion resistance to alkalis. The metal is therefore frequently used in the production and handling of caustic soda. In contrast, nickel is attacked by aqueous ammonia solutions.

Nickel absorbs hydrogen, especially when finely divided; hydrogen absorption increases with increasing temperature. Defined hydride compounds have not been characterized. Nitrogen is not absorbed by nickel nor does it combine directly with it, although there is evidence for a nitride Ni_3N.

[Top of Page]

2. Occurrence

Nickel ranks twenty-fourth in the order of abundance of elements in the earth's crust with an estimated concentration of 0.008 %. Although nickel is more abundant than copper, zinc, and lead there are relatively few nickel ore bodies of

commercial significance.

The economically important ores can be divided into two types, sulfide and oxide (or silicate). Nickel does not occur as native metal. World reserves of nickel (1988) were estimated at about 50×10^6 t by the U.S. Bureau of Mines. This estimate includes only ores which are economically recoverable at prevailing metal prices. Identified world resources in deposits containing 1 % Ni or more amount to over 130×10^6 t of nickel. About 80 % of the nickel in these resources is in laterite ore bodies, with only 20 % in sulfide deposits. The distribution of high – grade nickel reserves are detailed by country in Table 2, together with the corresponding 1988 mine production rates [13].

Table 2. World reserves of nickel [13]

Country	Reserves, 10^3 t	1988 Mine production, 10^3 t
Albania	180	10
Australia	1 270	74
Botswana	354	16
Brazil	666	15
Canada	8130	190
China	726	25
Colombia	558	21
Cuba	18 140	34
Dominican Republic	517	23
Finland	80	11
Greece	454	12
Indonesia	3 200	58
New Caledonia	4 535	56
Philippines	408	8
Rep. of South Africa	2 540	34
Former Soviet Union	6 620	186
Former Yugoslavia	158	4
Zimbabwe	77	11
World total	48 980	788

Nickel-containing manganese nodules, which occur in vast quantities on the seabed at depths between 3500 and 4000 m, typically contain 0.5 – 1.5 % Ni. While not currently economically viable as a source of nickel, these deposits will undoubtedly become an increasingly important nickel resource in the future.

The United States has significant quantities of low-grade nickel resources such as the laterite ores of Oregon and northern California. However, none of these ores was considered as an economic nickel reserve by the Bureau of Mines at 1988 metal prices, and consequently they are omitted from Table 2.

2.1. Nickel Minerals

The most important nickel-containing minerals occurring in nickel deposits are listed in Table 3, together with their chemical compositions [1]. Some are relatively uncommon, and only pentlandite, garnierite, and nickeliferous limonite are of economic significance. The term garnierite is commonly used as a generic name for a series of mixed nickeliferous silicates with a wide range of nickel contents, and can include colloidal mixtures of silica and nickel hydroxide. Nickeliferous limonite is the term used to describe poorly crystalline nickel-bearing ferric oxides of which the main constituent is goethite (α-FeO · OH).

Table 3. Principal nickel minerals [1]

Mineral	Ideal formula	Nickel content, %
Sulfides		
Pentlandite	$(Ni,Fe)_9S_8$	34.22
Millerite	NiS	64.67
Heazlewoodite	Ni_3S_2	73.30
Polydymite	Ni_3S_4	57.86

Siegenite	$(Co,Ni)_3S_4$	28.89
Violarite	Ni_2FeS_4	38.94
Arsenides		
Niccolite	NiAs	43.92
Rammelsbergite	$NiAs_2$	28.15
Gersdorffite	NiAsS	35.42
Antimonides		
Breithauptite	NiSb	32.53
Silicates and oxides		
Garnierite	$(Ni,Mg)_6Si_4O_{10}(OH)_8$	≤ 47 %
Nickeliferous limonite	$(Fe,Ni)O(OH) \cdot nH_2O$	low

Pyrrhotite ($Fe_{n-1}S_n$) is not included in the list of nickel minerals because it is an iron sulfide, and nickel is not essential to its composition. In pyrrhotites from different ore bodies the composition varies from FeS to Fe_7S_8. Small amounts of nickel may substitute for the iron, making some pyrrhotite nickeliferous, independently of any particles of pentlandite they may contain.

2.2. Sulfide Ores

Sulfide nickel ores consist principally of nickeliferous pyrrhotite (Fe_7S_8), pentlandite $(Ni, Fe)_9S_8$, and chalcopyrite ($CuFeS_2$). Other minerals which occur in small but significant amounts include magnetite (Fe_3O_4), ilmenite ($FeTiO_3$), pyrite (FeS_2), cubanite ($CuFe_2S_3$), and violarite (Ni_2FeS_4). Sulfide ores typically grade 0.4 – 2.0 % nickel, 0.2 – 2.0 % copper, 10 –30 % iron, and 5 – 20 % sulfur. The balance consists of silica, magnesia, alumina, and calcium oxide.

Pentlandite, the commonest of the sulfide minerals, probably accounts for 60 % of world nickel production. Nickeliferous pyrrhotite is normally the most abundant phase in a nickel ore. It contains nickel in solid solution (0.2 – 0.5 % Ni) in addition to very finely divided pentlandite inclusions. Chalcopyrite is the most important copper mineral, although cubanite is often present in lesser amounts.

Although the major minerals are the same in all large sulfide ore bodies, the relative amounts of pyrrhotite, pentlandite, and chalcopyrite vary widely. The relative amounts of the three minerals largely determine the choice of processing route.

In addition to nickel production, a large number of valuable byproducts can be recovered from sulfide ores, including copper, cobalt, the platinum group metals, gold, silver, selenium, tellurium, sulfur, and iron. Cobalt occurs principally in solid solution in pentlandite, at concentrations ranging from 1 to 5 % of the nickel content. Discrete particles of gold, silver, and platinum group metals are very rare, and these metals are normally found in solid solution in the sulfide phases. The treatment processes are nornally designed to yield optimum overall recovery of metal values.

Major sulfide ore bodies occur in Canada, the former Soviet Union, the Republic of South Africa, Australia, Zimbabwe, and Finland.

2.3. Oxide Ores

The oxidic ores of nickel are formed by a chemical concentration process that occurs as a result of the lateritic weathering of peridotite rock. Peridotite consists mainly of olivine, a magnesium iron silicate containing up to 0.3 % nickel. In many rocks the peridotite has been altered to serpentine, a hydrated magnesium silicate, prior to exposure to weathering. Olivine and serpentine are decomposed by groundwater containing carbon dioxide to form soluble magnesium, iron, and nickel, and colloidal silica. The iron rapidly oxidizes in contact with air and precipitates by hydrolysis to form goethite and hematite, which remain near the surface of the deposit. The dissolved nickel and magnesium, and the colloidal silica, percolate downwards in the laterite deposit, remaining in solution so long as the solution is acidic. When the solution is neutralized by reaction with rock and soil, nickel, silica, and some of the magnesium precipitate as hydrated silicates. This process is illustrated in Figure 1 [14].

Figure 1. Typical section through alaterite deposit

Complete separation of iron and nickel into distinct zones is never achieved. Some or even most of the nickel may in fact remain in the upper layer, which is thus enriched in iron and nickel, but depleted in magnesium and silica. Such material, consisting mainly of ferric oxide minerals, is described as limonitic. This type of ore is typically relatively rich in cobalt and

chromium. By contrast, in the silicate minerals, the separation of iron and nickel is more complete, and the nickel is present in silicate minerals with a high magnesia content. Both types of material are almost always found in a laterite deposit, but in widely differing proportions.

The differences between limonitic and silicate minerals influence the methods by which they are treated for nickel recovery (Fig. 1). The silicates, which are chemically and mineralogically heterogeneous and require a very flexible processing method, are normally treated by pyrometallurgical processes. The limonites on the other hand are relatively homogeneous in composition and mineralogy and are well suited to hydrometallurgical treatment.

The type of weathering which dissolves silica and metallic elements from rock to produce limonitic and silicate nickel ores occurs most frequently in tropical climates with high rainfall, and with decomposing vegetable matter to provide organic acids and carbon dioxide in the groundwater. Oxide nickel mineral deposits are currently exploited in Australia, Brazil, Cuba, the Dominican Republic, Greece, Indonesia, the Philippines, New Caledonia, Yugoslavia, the United States, and the former Soviet Union. The laterite deposits in Oregon and California were formed when the climate was subtropical in past geologic epochs.

2.4. Economic Trends

Although 80 % of the world's known nickel resources on land are in oxide ore bodies, only 40 % of nickel production comes from this source. The greater part of the nickel produced is recovered from sulfide ores. This situation has arisen from the influence of political, geographic, technical, and economic factors. Sulfide ore deposits lie mostly in politically stable countries and close to the major nickel markets. The nickel content of sulfide ores can be concentrated relatively easily and cheaply by physical methods, while oxide ores must be treated in bulk. The potential for recovering the more numerous and valuable byproducts also favors the exploitation of sulfide ore. However, the grades of sulfide ores are continually declining as the richer ores are consumed, and the cost of underground mining, particularly labor costs, is continually increasing. Inevitably therefore, oxide ore bodies, which are all relatively uniform in grade and can be surface mined, must in future support a larger share of nickel production.

Unfortunately, the production of nickel from oxide ores by the established processes consumes two to three times as much energy as the processing of sulfide ores. Nickel oxide ore treatment is therefore very sensitive to fuel oil and electrical power costs. A major expansion in the exploitation of oxide ores occurred in the decade prior to 1973 when fuel oil prices were low. Many of the new laterite treatment plants built in this period became uneconomic after the oil price increase in 1973, and as a result there was little or no increase in the proportion of nickel produced from oxide ores between 1975 and 1990.

Several international mining industry consortia evaluated the feasibility of recovering nickel from deep sea manganese nodules during the 1970s, and potential mining techniques were developed and tested (see also ⟶ Manganese and Manganese Alloys – Processing of Manganese Nodules and Encrustations). However, processing of the nodules to separate and recover the metals proved to be significantly more expensive than for land-based ores [15], [16]. The international legal aspects of ownership of these deep sea resources were the subject of the 11th Session of the Third U.N. Conference on the Law of the Sea, which ended in April 1982 with only a partial agreement which several major participants refused to sign [17]. These developments, in conjunction with low nickel prices, essentially killed any serious consideration of deep sea nodules as a source of nickel during the 1980s. Development of this resource on a significant scale is therefore unlikely before the next century.

[Top of Page]

3. Beneficiation of Nickel Sulfide Ores [1], [18]

The low metal content of present-day nickel sulfide ores renders them unsuitable for either direct smelting or direct hydrometallurgical processing. Because the sulfide minerals usually occur as distinct grains in the rock matrix, these ores are amenable to a mechanical upgrading in which much of the rock content can be rejected. The metal content of the ore is concentrated by a physical treatment such as comminution to liberate the metal sulfide grains, followed by froth flotation or magnetic separation to recover a metal-rich concentrate [19].

In principle it is possible to produce separate nickel (pentlandite), copper (chalcopyrite), and iron (pyrrhotite) concentrates. However, a clean separation of pentlandite from pyrrhotite is difficult in practice since pyrrhotite typically contains intergrown inclusions of pentlandite as well as nickel in solid solution in the pyrrhotite. In fact pyrrhotite often contains 0.5 – 1 % Ni that cannot be separated by physical methods. The relatively high nickel content in pyrrhotite makes it difficult to achieve high yields of nickel from the ore unless the pyrrhotite is processed to recover its nickel content, and conversely the presence of nickel makes it difficult to obtain a marketable iron product from the pyrrhotite.

Most nickel producers, outside Canada, make no attempt to obtain separate nickel, copper, and iron concentrates and produce a bulk concentrate that contains pentlandite, pyrrhotite, and chalcopyrite as smelter feed. In Canada, both the major producers separate a large part of the pyrrhotite from pentlandite and chalcopyrite, and Inco further separates the pentlandite and chalcopyrite into separate nickel and copper concentrates. Even where the bulk of the pyrrhotite can be separated from pentlandite, residual pyrrhotite in the nickel concentrate still contributes a major part of the sulfur content.

In response to ever tighter constraints on sulfur dioxide emissions from smelters during the 1970s and 1980s, the Canadian companies have made increased pyrrhotite rejection from smelter feed a major priority, and substantial improvements have been achieved. A pyrrhotite concentrate was treated by Inco for many years for nickel and iron oxide recovery. However, environmental constraints on sulfur dioxide emissions have rendered the process obsolete, and pyrrhotite concentrates are now largely stockpiled, since none of the known treatment methods that avoid sulfur dioxide production is economic.

Pyrrhotite can be separated from pentlandite and chalcopyrite either by using its ferromagnetic properties or by flotation. Not all pyrrhotite is ferromagnetic, although in ores from the Sudbury, Ontario area the magnetic monoclinic form predominates

over the paramagnetic or “nonmagnetic” hexagonal form [20]. In general, pyrrhotite containing less sulfur than $Fe_{0.87}S$ is nonmagnetic. This material can usually be separated from pentlandite by flotation.

Nickel or nickel – copper concentrates typically range in grade from 5 to 15 % Ni + Cu, depending on the degree of pyrrhotite rejection achieved. An exceptionally high-grade concentrate, containing 28 % Ni and consisting largely of pentlandite, is produced in limited amounts at Inco's Thompson, Manitoba operation.

One of the more complex nickel concentration process flow sheets is that operated by Inco at its Sudbury operation [21]. In the two primary concentrators, the Clarabelle mill and the Frood – Stobie mill, 50 000 t/d of ore, grading 1.2 % Ni and 1.2 % Cu, is ground to a particle size of ca. 200 µm and treated by magnetic separation and flotation with a sodium amyl xanthate reagent to produce 5000 t/d of a bulk nickel – copper concentrate and 8000 t/d of a pyrrhotite concentrate. Metallurgical data for the Clarabelle mill are given in Table 4.

Table 4. Metallurgical data for the magnetic separation and flotation of nickel ore (Clarabelle mill, Inco) [21]

	wt %	Analysis, %					
		Cu	Ni	Pyr *	Cu	Ni	Pyr *
Ore	100	1.32	1.40	18.9	100	100	100
Magnetic concentrate	26	0.62	1.65	62.7	12	30	84
Flotation concentrate	8	14.4	11.6	15.9	84	64	7
Tails	66	0.07	0.13	2.5	4	6	9

* Pyr = Pyrrhotite.

The two primary concentrates are further upgraded in the Copper Cliff mill. The bulk nickel – copper concentrate is separated by flotation into separate nickel and copper concentrates by using lime and sodium cyanide at 30 – 35 °C to depress pentlandite and pyrrhotite. Under these conditions about 92 % of the copper is recovered to a concentrate grading 29 % Cu and 0.9 % Ni. About 98 % of the nickel and 92 % of the pyrrhotite are rejected to the separator tails, which grade 13 % Ni and 2.0 % Cu.

The Clarabelle rougher pyrrhotite concentrate is treated to separate residual chalcopyrite and pentlandite by grinding to ca. 74 µm followed by magnetic separation and flotation. A magnetic, cleaner pyrrhotite concentrate, a bulk nickel – copper concentrate, and a nonmagnetic pyrrhotite tail are produced. The nonmagnetic tails stream (1 % Cu, 2 % Ni, and 30 % pyrrhotite) is further treated, by regrinding and flotation in the pyrrhotite rejection circuit, for final recovery of pentlandite and chalcopyrite before it is discharged to the tailings pond. Overall, about 80 % of the pyrrhotite content of the ore is rejected from smelter feed to the pyrrhotite concentrate and tails. Metallurgical data for the Copper Cliff mill are given in Table 5.

Table 5. Metallurgical data for the upgrading of pyrrhotite and copper – nickel concentrate (Copper Cliff mill, Inco) [21]

	wt %	Analysis, %					
		Cu	Ni	Pyr *	Cu	Ni	Pyr *
Feed	100	4.58	4.42	49.6	100	100	100
Copper concentrate	13	29.2	0.91	8.4	83	3	2
Nickel concentrate	29	2.28	12.8	43.0	14	85	25
Pyrrhotite concentrate	33	0.11	0.96	84.4	1	7	57
Tails	25	0.36	0.91	32.3	2	5	16

* Pyr = Pyrrhotite.

Falconbridge at its Strathcona mill in the Sudbury basin treats ore containing 1.5 % Ni and 1.1 % Cu by grinding and flotation to produce a nickel – copper concentrate grading 6.7 % Ni and 5.6 % Cu at an average recovery of 83 % Ni and 93 % Cu [22-24]. A large part of the pyrrhotite content of the ore is rejected directly to the tailings pond. The separation of the nickel and copper in the bulk concentrate is carried out in the matte refining process after smelting.

The ore mined by Inco at Thompson, Manitoba consists of pentlandite and pyrrhotite with only a small amount of chalcopyrite (2.7 % Ni, 0.2 % Cu, 22 % pyrrhotite). Since the pyrrhotite contains 78 % of the sulfur but only 5.5 % of the nickel, a high degree of pyrrhotite rejection is feasible without seriously decreasing the nickel recovery [25]. The ore is ground and floated to recover a nickel – copper concentrate and reject 90 % of the gangue and 60 % of the pyrrhotite to tails. The nickel – copper concentrate is treated by flotation to separate first a copper concentrate, and then by magnetic separation and flotation to recover a high-grade (28 % Ni) pentlandite concentrate. The tailings stream from these steps forms the main nickel concentrate smelter feed (11 % Ni, 0.4 % Cu). The overall recovery of nickel to the nickel and pentlandite concentrates is about 87 %, while another 5 % of the nickel reports to the copper concentrate. Over 60 % of the pyrrhotite is rejected to

tailings with only 8 % of the nickel.

At the BCL nickel – copper mine in Botswana the pyrrhotite/pentlandite ratio in the ore averages about 13 : 1 and the pyrrhotite contains over 30 % of the nickel either in solid solution or as small pentlandite inclusions. Consequently, high nickel recoveries can only be achieved by recovering the nickel from pyrrhotite. This is achieved by producing a bulk pentlandite – pyrrhotite – chalcopyrite concentrate, with a typical composition of 2.8 % Ni and 3.2 % Cu [26].

Modern nickel concentrators are largely automated and are equipped with process control systems based on on-line X-ray analysis of process streams [27].

[Top of Page]

4. Pyrometallurgy of Nickel Concentrates [1], [28-32]

Over 90 % of the world's nickel sulfide concentrates are treated by pyrometallurgical processes to form nickel-containing mattes. Production capacities and composition of the feed concentrate and product matte are listed in Table 6 for several major nickel smelters.

Table 6. Nickel sulfide smelters [30-32]

Smelter	Feed concentrate, %				capacity, t/a Ni
	Ni	Cu	Ni	Cu	
Inco, Copper Cliff	13	2.7	63	15	110 000
Inco, Thompson	10.5	0.4	73	3	50 000
Western Mining	11.4	0.85	72	5	60 000
Falconbridge	6.7	5.6	40	34	45 400
Outokumpu	8 – 9	2 – 4	64	26	18 000
BCL, Botswana	2.8	3.2	38	40	20 000
Rustenburg	3.2	2.0	47	27	19 000
Bindura	10.6	3.4	70	20	14 400

The pyrometallurgical treatment of nickel concentrates includes three types of unit operation: roasting, smelting, and converting. In the roasting step sulfur is driven off as sulfur dioxide and part of the iron is oxidized. In smelting, the roaster product is melted with a siliceous flux which combines with the oxidized iron to produce two immiscible phases, a liquid silicate slag which can be discarded, and a solution of molten sulfides which contains the metal values. In the converting operation on the sulfide melt, more sulfur is driven off as sulfur dioxide, and the remaining iron is oxidized and fluxed for removal as silicate slag, leaving a high-grade nickel – copper sulfide matte.

In several modern operations the roasting step has been eliminated, and the nickel sulfide concentrate is treated directly in the smelter.

4.1. Roasting [33]

Roasting is basically a process in which the nickel sulfide concentrates are heated in an oxygen-containing gas, usually air, to a temperature (600 – 700 °C) at which oxygen oxidizes sulfide to sulfur dioxide and reacts with the metal values to form solid oxides, termed the calcine. The roasting step may also serve to preheat the charge for smelting.

The thermodynamic relationships between the metal sulfides and oxides provide the basis for the separation of iron from nickel, copper, and cobalt contained in the concentrate. The sulfides of iron, nickel, cobalt and copper are all in the same thermal stability range at the smelting temperatures (1200 – 1300 °C), but, in the presence of oxygen, each sulfide is unstable with respect to its corresponding oxide. Iron has the greatest affinity for oxygen, followed by cobalt, nickel, and copper. Consequently, if the nickel concentrate is roasted with a deficiency of oxygen the iron is oxidized preferentially, while virtually all of the nickel and copper remain as sulfides. Thus the degree of oxidation of the charge and the degree of elimination of sulfur can be controlled by regulating the supply of air to the roaster.

The degree of sulfur elimination achieved in the roasting step largely determines the grade of the matte produced as well as the losses of nickel and copper to the slag phase in the subsequent smelting operation. All the sulfur present in the calcine in excess of the amount needed to combine with the nickel, copper, and cobalt in the matte combines with iron, which therefore remains in the matte phase and lowers its nickel – copper – cobalt grade. The major constraint on achieving a high-matte grade in smelting is the increasing loss of nickel, copper, and cobalt to the slag phase. If all of the iron were to be oxidized in the roasting step so that it could be slagged off in the smelting stage and a high-grade matte produced directly, an increased amount of nickel, copper, and cobalt oxides would be formed in the roaster, and metal losses to the slag in smelting would increase substantially. Hence, each smelting operation seeks to operate at an optimum matte grade which gives the highest metal value recovery to the matte. The balance of the iron is removed in the converting step.

Normally only about 50 % of the pyrrhotite content of the nickel concentrate is oxidized in roasting, and under these conditions less than 5 % of the nickel and copper are oxidized, with the balance remaining as sulfides. The oxidation of

pyrrhotite to magnetite can be represented by the following reaction:

$$3\,Fe_7S_8 + 38\,O_2 \rightarrow 7\,Fe_3O_4 + 24\,SO_2$$

This reaction is strongly exothermic, and autogenous roasting, without the use of an external heat source, is practiced whenever possible.

In order to achieve effective roasting the furnace must provide good contact between the sulfide particles and the oxygen-bearing gas. The furnace system must also be able to provide close control of the degree of sulfur elimination. Both multihearth roasters and fluidized-bed roasters are in industrial use for nickel concentrate roasting. The use of traveling grate sintering machines, which were formerly widely used to prepare an agglomerated feed for blast furnace smelting, is now practiced only in the former Soviet Union.

The multihearth roasting furnace consists of a series of vertically superimposed circular hearths. Wet concentrate and smelting flux are charged to the upper hearth. A central rotating shaft drives rabble arms that extend across the roaster hearths, turning over the concentrate charge and transferring it via dropholes to the next lower hearth. Air, preheated by the combustion of natural gas, passes upwards through the hearths, heating the concentrate to ignition temperature and providing the oxygen required to burn the concentrate. The temperature is controlled by regulating the flow of air into the roaster.

Since the area of contact between the furnace gas and concentrate particles on the hearths is very limited, the total time required for roasting in this type of furnace is long, resulting in low throughput rates. A further disadvantage of the multihearth roaster is that low oxygen utilization and high air infiltration rates produce an off-gas with a low concentration of sulfur dioxide which is unsuitable for sulfuric acid production.

Multihearth roasters are still used in the Copper Cliff smelter of Inco in Ontario, which was built in 1930. A battery of 24 roasters can each treat 300 t/d of wet concentrate mixed with 75 – 90 t/d of siliceous flux. About 40 % of the sulfur content of the concentrate (13 % Ni, 2 – 3 % Cu, 30 % S, and 40 % Fe) is eliminated at a roasting temperature of 800 °C. Less than 5 % of the nickel and copper are oxidized. This operation is not thermally self-sustaining, due to high heat losses from the roaster, and natural gas is used to provide supplementary heating. The off-gas is cleaned to recover dust and is vented to a stack. The roasted calcine discharge from the bottom of the furnaces is conveyed directly to the reverberatory smelting furnaces [34].

The fluidized-bed roaster is a more recent development and has an improved gas – solids contact efficiency and a simpler construction (Fig. 2). The roasting furnace is a vertical chamber of circular cross section with a grate hearth through which the oxygen-bearing gas is blown. As nickel concentrate and smelting flux are fed to the chamber, the particles are suspended in the vertical air flow. Since each sulfide particle is in constant turbulent motion in the oxidizing atmosphere, roasting is uniform and rapid, with efficient heat transfer and oxygen utilization. Solids are discharged from the furnace either by overflow through a side port or by entrainment in the off-gas stream. The dust-laden gas may be passed through waste-heat boilers to recover its sensible heat. The cleaned off-gas stream contains a high concentration of sulfur dioxide, which can be converted to sulfuric acid.

Figure 2. Cutaway view of a fluidized-bed roaster

Fluidized-bed roasting of nickel concentrates is practiced by Inco at the Thompson smelter in Manitoba and at Copper Cliff, where 10 % of the nickel concentrates are processed in fluidized-bed roasters, and by Falconbridge at its smelter in Ontario. The Thompson smelter operates five fluidized-bed roasters with a combined capacity of 3800 t/d of concentrate, while the Falconbridge smelter operates two roasters with a combined capacity of 2000 t/d of concentrate [22], [35].

In the Falconbridge smelter a slurry (75 % solids) of nickel – copper concentrate (6.7 % Ni, 5.6 % Cu, 30 % S, 40 % Fe) in water is fed directly to the roaster. Siliceous flux is added separately. Sulfur elimination ranges from 50 to 60 % at a roasting temperature of 600 – 650 °C. The operation is thermally autogenous, and the water contained in the feed slurry serves as a heat sink to control the bed temperature. Oxygen utilization is essentially 100 %. About 85 % of the calcine leaves the roaster in the off-gas stream which is treated in a series of cyclones, gas coolers, and electrostatic precipitators for solids recovery. The solids recovered from the gas cleaning system are combined with the coarser roaster bed overflow calcine, for charging to the electric smelting furnaces [24].

4.2. The Smelting Process

In the treatment of nickel sulfide ores and concentrates the function of the smelting process is to eliminate the gangue minerals and most of the iron sulfide and to concentrate the metal values into a high-grade nickel – copper matte containing 0.5 – 3.0 % Fe and 6 – 22 % S. Unlike copper, nickel metal cannot be produced by the oxidation of the sulfide at a practical smelting temperature (up to ca. 1400 °C).

When a mixture of metal sulfides, iron oxide, gangue, and siliceous flux are melted together, the iron oxide, gangue, and silica form a slag layer that floats on the heavier, molten sulfide or matte phase. The two immiscible layers are separated and

the slag is discarded.

The smelting process for nickel sulfide concentrates is normally carried out in two stages: primary smelting and converting. The oxidizing, slagging, and removal of iron in stages is critical to the efficiency and economics of smelting operations. If most of the iron were to be oxidized in the roaster and then slagged in a single smelting step, a matte high in nickel and low in iron would be produced. However, as noted above, significant amounts of the nickel and copper sulfides would also be oxidized in the roaster, and these oxides would be lost to the slag in the smelting step. Slag can also mechanically entrain droplets of matte and these losses will also increase with matte grade. Thus if a high-grade matte were to be produced in one step, the overall recovery of nickel would be low.

Provided that only about half the iron is oxidized in the initial roasting step, only 5 % of the nickel and copper sulfides are oxidized. In fact only a small amount of these oxidized metals will be lost to the slag because the oxides react with residual iron sulfides in the smelting process to produce the corresponding sulfides, which return to the matte phase.

$$9\,NiO + 7\,FeS \rightarrow 3\,Ni_3S_2 + 7\,FeO + SO_2$$

$$Cu_2O + FeS \rightarrow Cu_2S + FeO$$

Thus a low-grade, high-iron furnace matte is produced and only a small amount of nickel is lost to the slag as oxide when the nickel concentrate is treated in separate roasting and smelting steps.

The iron remaining in the furnace matte is oxidized and slagged in the secondary smelting step (converting). Since the slag produced in the converting stage, in which a high-grade, low-iron matte is produced, has a high nickel and copper content, it is returned to the primary smelting stage where the metal values are recovered by the reaction of the oxides with iron sulfide and by the settling of entrained droplets of matte. Thus the two-stage smelting process allows the production of a high-grade, low-iron nickel matte, and a high-iron slag of low metal grade which can be discarded without significant loss of metal values.

4.2.1. *Primary Smelting*

The primary smelting step is carried out in a variety of furnaces, including reverberatory, electric, and flash furnaces, which provide a wide variety of smelting conditions. Chemical losses of nickel and copper to the slag increase with the oxidation potential of the system. Thus metal losses to slag are much higher in the flash smelting furnace, in which the roasting step is combined with the primary smelting step, and smelting conditions are strongly oxidizing, than in the electric furnace, where smelting is carried out under reducing conditions. Consequently, slag from the flash smelting process must be treated in a separate step to recover the contained metal values, while slag from the electric furnace or reverberatory furnace smelting processes can be discarded without further treatment.

A typical furnace matte containing 10 % Ni, 65 % Fe, and 25 % S melts at ca. 950 °C, and nickel sulfide itself melts at ca. 790 °C. The melting point of a fayalite slag with an iron to silica ratio of about 7 : 3 is 1200 °C, although the slag melting point can be reduced to 1100 °C by the addition of a few percent of lime and alumina. With this type of slag, smelting is carried out at ca. 1200 °C. However, when significant levels of magnesia are present in the nickel concentrate or ore the melting point of the slag may be as high as 1260 °C, and smelting is then carried out at ca. 1400 °C [36-38].

Magnetite, which is formed in the partial roasting of the concentrates, reacts in the primary smelting step with the remaining iron sulfides and silica flux to form fayalite:

$$3\,Fe_3O_4 + FeS \rightarrow 10\,FeO + SO_2$$

$$2\,FeO + SiO_2 \rightarrow 2\,FeO \cdot SiO_2$$

The presence of magnetite in slags and mattes not only affects the chemistry of the smelting operation, but has an important effect on the smelting furnace. Magnetite is formed under strongly oxidizing conditions and its formation is favored by low operating temperatures and by silica-deficient slags. The magnetite content of slags from the more oxidizing reverberatory and flash smelting furnaces is usually above 10 %, with the content increasing with matte grade, while slags from reduction smelting electric furnaces typically contain less than 5 % magnetite. Magnetite tends to settle out in the bottom of the smelting vessel and accretions can severely reduce the operating capacity of the furnace. Consequently it is always desirable to minimize the formation of magnetite in the smelting process.

Reverberatory Furnace Smelting. In the reverberatory furnace, fossil fuel (pulverized coal, oil, or natural gas) is burned separately from the material being smelted. The furnace is a long rectangular structure with an arched roof and burners at one end and in the roof. A large part of the heat from the combustion gas radiates directly to the charge lying in the hearth below. A further substantial part of the heat is reflected from the walls and roof of the furnace into the charge. Solid charge is fed through vertical fettling pipes mounted in the roof along each side of the furnace. As the charge melts it flows towards the center of the furnace. Molten converter slag is introduced into the furnace at the firing end.

Slag is tapped from the end of the furnace opposite the burners, while matte is tapped from the side. This type of furnace has a low energy efficiency since the off-gas stream carries nearly 50 % of the heating value of the fuel. Waste-heat boilers or heat exchangers are used to recover heat from the off-gases.

The reduction of the magnetite formed in the roaster to ferrous oxide is not complete in the reverberatory furnace, and slags contain up to 7 % magnetite. Scrap iron or ferrosilicon is often added to control the formation of magnetite to minimize metal losses to the slag and to prevent magnetite buildup in the furnace hearth.

Inco uses two reverberatory furnaces equipped with roof-mounted oxyfuel burners for the primary smelting of nickel concentrates at its smelter in Copper Cliff, Ontario. Each furnace treats 1500 t/d of partially oxidized concentrate (13 % Ni,

2.7 % Cu) which is transferred at 700 °C from the multihearth roasters, together with 700 t/d of recycled molten converter slag. Oxygen enrichment of the combustion air supplied to the oxyfuel burners not only increases fuel utilization efficiency but also substantially increases the capacity of the furnace [34], [39-43].

The furnace matte contains 30 – 35 % nickel plus copper, together with the precious metals content of the charge. The reverberatory slag, which normally analyzes 0.2 % Ni, 0.1 % Cu, 0.1 % Co, 38 % Fe, and 36 % SiO_2, is discarded. The matte is tapped at 1150 °C and blown with oxygen-enriched air (30 % O_2), in one of 14 Peirce – Smith converters, to a high-grade, sulfur-deficient matte containing 78 % Ni and Cu and 20 % S. The converter slag, typically containing 2.3 % Ni and Cu, 50 % Fe, and 25 % SiO_2, is recycled to the reverberatory furnace for recovery of the contained nickel and copper [42].

Electric Furnace Smelting. The energy required for smelting may be obtained from electrical power as an alternative to burning fossil fuels or sulfides in air or oxygen. The use of an electric furnace for nickel sulfide smelting is favored when the cost of electrical energy is low or when the required smelting temperature is high, for example, when the concentrate contains high levels of magnesia.

Heating of the bath is achieved by passing a three-phase electrical current through a circuit consisting of carbon electrodes immersed in the slag layer, which has a high electrical resistance (submerged arc technique). Electric furnaces used for nickel – copper matte smelting are either rectangular with six electrodes in line or circular with three electrodes in triangular configuration. The consumable electrodes are made of carbon and are either prebaked or are of the self-baking Soederberg type.

The charge of concentrate (or calcine) and flux is fed through the roof. Thus a layer of unsmelted charge covers the slag giving it a “cold top”. The concentrate or calcine gradually settles into the slag as it melts and then separates into slag and matte layers. The slag and matte are tapped intermittently, as required. Since there is no fuel combustion in an electric furnace the quantity of off-gas is much less than from a reverberatory furnace and heat and dust recovery from the off-gas is therefore easier.

Electric furnace smelting of nickel concentrates is practiced by Inco at its Thompson, Manitoba, operation; by Falconbridge at Sudbury, Ontario; by the Severonikel Combine in the former Soviet Union; by Rustenburg Platinum, Impala Platinum, and Western Platinum in the Republic of South Africa; and by Bindura Nickel in Zimbabwe. The Canadian operations treat partly roasted concentrate calcines, while Bindura and the platinum producers treat nickel – copper concentrates directly. The Severonikel electric furnace smelter treats high-grade ore from Norilsk (3.5 % Ni, 3.5 % Cu) directly [44]. Current industrial practice is illustrated by the following examples.

In the Rustenburg Refiners smelter [45] in the Republic of South Africa, pelletized nickel – copper concentrate, containing 3.2 % Ni, 2 % Cu, 15 % Fe, 39 % SiO_2, 15 % MgO, 3 % CuO, 6 % Al_2O_3, 9 % S, and ca. 130 g/t precious metals, is mixed with a lime flux and smelted directly in a 19.5 MVA electric furnace. About 98 % of the nickel and 97 % of the copper and most of the precious metals contained in the concentrate are recovered to a matte containing about 17 % Ni, 10 % Cu, 40 % Fe, and 27 % S. The electric furnace slag, containing 0.1 % Ni and 0.06 % Cu, is tapped at 1350 °C and discarded. The matte is tapped at 1180 °C and converted in Peirce – Smith converters to a product analyzing 48 % Ni, 27 % Cu, 1.5 % Fe, and 20 % S, again with high recovery of the precious metals to the matte.

The Falconbridge smelter in Sudbury, Ontario, which was built in 1978 on similar lines to Inco's Thompson smelter, is a good example of the modern large-scale application of fluidized-bed roasting and electric furnace smelting of nickel – copper concentrates (Fig. 3). The smelter contains two roaster – electric furnace lines, each of which was designed to treat up to 1250 t/d of nickel – copper concentrate (6.7 % Ni, 5.6 % Cu). The electric furnaces are each rated at 33 MVA and have a six-in-line electrode configuration. The electrodes are of the Soederberg self-baking type. Typical furnace operating conditions are as follows [24], [46], [47]:

Concentrate feed rate	900 t/d
Power consumption	1.2 GJ/t solid charge
Slag temperature	1230 °C
Matte temperature	1130 °C
Off-gas temperature	700 °C
Calcine depth	500 mm
Slag depth	1500 mm
Matte depth	700 mm
Bottom buildup	150 mm
Electrode immersion	250 mm
Off-gas volume	28 300 m^3/h (STP)

Figure 3. Flow sheet of the Falconbridge smelter

a) Gas scrubbing and calcine recovery; b) Acid plant; c) Converter; d) Electric furnace

Roaster calcine together with the flux added prior to roasting, at about 600 °C, is conveyed directly to the furnace and added

to the bath through fettling tubes mounted in the furnace roof. Recycle dusts and scrap together with reductants are added to the calcine conveyors. Converter slag is fed to the furnace through a launder above the matte-tapping end of the furnace.

Coke is added to the charge as a reductant, at a rate of 2.5 wt % of the concentrate, to improve metal recoveries and to reduce magnetite formation. The use of coke reductant and operation of the furnace under “black top” conditions results in a significant power saving compared with open-bath operation under oxidizing conditions. (1.2 GJ/t versus 1.5 GJ/t of solid charge).

The electric furnace slag, typically containing 0.12 % Ni, 0.20 % Cu, and ca. 4 % magnetite, is tapped at 1230 °C and is transferred in slag pots to a disposal area. The furnace matte, which normally contains 24 % Ni + Cu, is tapped at 1130 °C and is transferred to one of four Peirce – Smith converters where it is blown with air to produce a matte containing 74 % Ni + Cu, 1 % Co, 2.5 % Fe, and 23 % S. The converter matte is cast, crushed, and shipped to the Falconbridge refinery in Norway. The converter slag is recycled to the electric furnace, and the converter off-gases are cleaned in electrostatic precipitators and vented to a stack.

Flash Smelting. In flash smelting, a finely ground sulfide concentrate is smelted by burning some of its sulfur and iron content while the sulfide particles are suspended in the oxidizing atmosphere. The concentrate is roasted and smelted in a single process step. The predried concentrate and flux materials are injected with preheated oxygen-enriched air or commercial oxygen into the reaction shaft of a specially designed furnace. The exothermic heat of reaction of the iron sulfide with oxygen provides the energy to heat the particles to smelting temperature. The smelting temperature and the grade of matte formed are both controlled by adjusting the ratio of the amount of oxygen supplied to the furnace to the throughput rate of concentrate. In current practice, which uses oxygen-enriched air, the process can be thermally autogenous, and the addition of a fossil fuel is not generally required.

The flash smelting process was developed independently by Inco in Canada and Outokumpu in Finland, shortly after World War II. In both cases it was applied commercially to the treatment of copper concentrates. The Inco process uses commercial oxygen (95 %) while the Outokumpu process initially used air, augmented by fuel oil, as the oxidant and energy sources. The Outokumpu process was first applied commercially to the treatment of nickel concentrates in 1959. Oxygen enrichment of the combustion air was introduced by Outokumpu in 1971 and resulted in several major improvements in furnace performance. The Inco flash smelting process was successfully tested on a full production scale for the treatment of nickel concentrate in 1976, and will be utilized in the modernization of the Copper Cliff smelter scheduled for the early 1990s (see Section Environmental Aspects of Nickel Smelting). In addition to its own installation at Harjavalta in Finland, the Outokumpu flash smelting process for nickel has been adopted by the Western Mining Corporation in Australia, by BCL in Botswana, and by the Norilsk Combine in the former Soviet Union. The Outokumpu flash smelting process for copper has been adopted in about 30 operations worldwide [48], [49].

The Outokumpu flash smelting furnace, essentially an upright U in shape, consists of a vertical reaction shaft, a horizontal reverberatory settler hearth, and a vertical gas uptake shaft (Fig. 4). Predried nickel concentrates and fluxes are mixed with oxygen-enriched air and injected into the furnace by means of the concentrate burner mounted at the top of the reaction shaft. The resulting suspension spreads over the area of the reaction shaft. At operating temperatures, ignition of the iron sulfides occurs instantly, and the following exothermic reaction with oxygen provides all the heat required for smelting:

Figure 4. Cutaway view of an Outokumpu flash smelting furnace

a) Concentrate burner; b) Uptake; c) Reaction shaft; d) Slag; e) Matte; f) Settler

$$2\,FeS + 3\,O_2 \rightarrow 2\,FeO + 2\,SO_2$$

The nickel and copper sulfides melt to form a matte, while the iron oxide combines with silica flux to form a fayalite slag. Separation of the molten particles from the combustion gases occurs as the gas stream leaves the reaction shaft. The melt collects in the settler, where the matte and slag form separate layers and are tapped at opposite ends of the furnace.

Nickel flash furnace mattes typically grade 50 – 55 % Ni + Cu, and the grade is controlled by adjusting the ratio of oxygen to concentrate in the furnace. The furnace mattes are treated in Peirce – Smith converters with oxygen-enriched air to produce a high-grade matte product. The converter slag is either recycled to the flash furnace or treated directly in a slag cleaning furnace to recover the contained metal values. The composition of converter matte varies between smelters. The final sulfur content is adjusted in accordance with the requirements of the subsequent refining process. Thus at Harjavalta the matte is blown to a sulfur content of only 4 – 7 %, while the other smelters produce matte containing about 20 % S.

When oxygen-enriched air is used to produce a high-grade furnace matte, operating temperatures are sufficiently high to reduce magnetite formation and prevent significant magnetite accretions building up in the furnace. Inevitably, when a high-grade matte is produced under oxidizing conditions the slags contain too high a level of metal values to be discarded. Nickel flash furnace slags are generally cleaned by reduction and settling in an electric furnace, with coke as the reductant. The Western Mining (WMC) flash furnace in Australia has been modified by the extension of the settler beyond the gas uptake shaft [50], [51]. This extension to the settler hearth contains two sets of electrodes and serves as a continuous slag cleaning furnace. The furnace slag tapped from the extension is sufficiently low in metal values to be discarded. At the BCL smelter in Botswana, which treats a very low-grade concentrate and consequently has a high slag to matte ratio, slag losses are controlled in the settler itself by the addition of lump coal, which floats on the surface of the slag and reduces the metal oxides [26], [52]. The slag is further cleaned in two electric furnaces connected in series before being discarded. Metallurgical data for three flash smelting operations are presented in Table 7.

Table 7. Metallurgical data for flash smelters [50-53]

Smelter		Outokumpu	BCL	WMC
Capacity, t/a				
concentrate		190 000	800 000	600 000
Concentrate, %	Ni	8 – 9	2.8	11.4
	Cu	2 – 4	3.2	0.9
	Fe	24 – 27	43.5	38
	S	19 – 22	31.0	32
Furnace matte, %	Ni	33	15	44
	Cu	19	17	3
	Fe	18		27
	S	25		22
Converter matte, %	Ni	58	36	72
	Cu	32	40	5
	Fe	0.5	< 1	< 1
	S	6	20	21
Discard slag, %	Ni	0.15	0.15	0.28
	Cu	0.32	0.34	0.08
Smelter recovery, %		95	91.5	96

Off-gases leave the flash furnace through the uptake shaft and enter a waste-heat boiler where the heat content of the gas is recovered as high-pressure steam. The gas, which has a high sulfur dioxide content, is cleaned in electrostatic precipitators to recover entrained dust. The cleaned gas stream can be used as a feed to a sulfuric acid plant, for liquid sulfur dioxide recovery, or can be reduced to elemental sulfur with a fossil fuel.

The flash smelting process is particularly suited to the application of automated process control. The major control parameter is the ratio of oxygen in the combustion air to concentrate throughput. This parameter not only controls the degree of oxidation of the sulfides but also the grade of the matte and the operating temperature. The process is thus controlled by adjusting the flow rates of both combustion air and commercial oxygen, in relation to the concentrate feed rate. The slag composition is controlled by the rate of addition of flux materials to the concentrate in the furnace feed blend. Control of the process can thus be fully computerized [53].

4.2.2. *Matte Converting [54-56]*

In the converting step, iron sulfide is removed from the molten, low-grade furnace matte by oxidation and slagging. The slag, which contains high levels of nickel and copper, is returned to the primary smelting furnace for recovery of metal values. The high-grade, low-iron nickel – copper matte, which typically contains 20 % S, less than 1 % Fe, and also any precious metals present in the original concentrates, is the final product of the smelting process.

Converting is a batch operation. The horizontal side blown converter, known as the Peirce – Smith converter (Fig. 5), is normally used for the treatment of nickel furnace mattes, although top blown rotary converters are used in some modern plants, particularly for low production rates. Air or oxygen-enriched air is blown through the molten matte to form iron oxides and remove sulfur as sulfur dioxide. The iron oxides combine with added silica flux to form an iron silicate slag:

Figure 5. Cutaway view of a Peirce – Smith side blown converter

a) Tuyere pipes; b) Pneumatic punchers; c) Hood; d) Flux gun

$$2\,FeS + 3\,O_2 \rightarrow 2\,FeO + 2\,SO_2$$

$$2\,FeO + SiO_2 \rightarrow 2\,FeO \cdot SiO_2$$

A substantial amount of magnetite is also formed in the conversion process.

Converter slags contain 20 – 35 % silica, with the balance being iron oxides. Silica in the slag combines with iron(II) oxide, thus preventing further oxidation to magnetite. Slags low in silica contain large amounts of magnetite. Typically, up to one-third of the iron may be in the iron(III) state in a 20 % silica slag, while a slag with 35 % silica contains less than 15 % magnetite. Magnetite formation is useful in converting since it can be made to coat the inside of the brick-lined furnace and thus protects it from erosion and corrosion by the slag [57], [58].

The oxidation of iron sulfide is strongly exothermic and much of the heat generated in the conversion process can be utilized

to melt additional ore or concentrate feed or recycled scrap materials. Since the throughput of a converter is almost directly proportional to the amount of oxygen blown through the charge, its capacity can be raised substantially by enriching the air with oxygen. In addition to increasing the converting rate, oxygen enrichment of the air permits the treatment of additional cold charge, and in fact the addition of cold charge is essential to control the bath temperature when oxygen-enriched air is used. Up to 3 t of cold charge materials can be smelted for each tonne of oxygen supplied.

4.3. Environmental Aspects of Nickel Smelting

During the 1970s and 1980s the nickel industry responded to increasing public concern over smelter emissions of sulfur dioxide to the environment by replacing outdated process equipment, such as multihearth roasters, sinter machines, blast furnaces, and reverberatory furnaces, by processes such as fluidized-bed roasting, electric furnace smelting, and flash furnace smelting, which are more energy efficient and environmentally cleaner.

However, while the technology is available to produce sulfuric acid economically from sulfur dioxide in the high-strength off-gas streams produced by the modern smelting techniques, there is not always a market for large amounts of acid within an economic shipping distance of the nickel smelter. Thus, although the Inco and Falconbridge smelters in the Sudbury area of Ontario do convert a substantial amount of their sulfur dioxide to acid, more remote operations, including Inco's smelter at Thompson, Manitoba, Western Mining's smelter in Western Australia, and the BCL smelter in Botswana, vent SO_2-containing off-gases to the atmosphere. In fact the BCL smelter was designed with the capability to convert sulfur dioxide to elemental sulfur by reduction with fuel oil. However, this process proved uneconomic when oil prices increased in the early 1970s and it has never been operated. A similar circuit that uses natural gas to reduce sulfur dioxide to sulfur is in operation at the Norilsk flash furnace smelter in the former Soviet Union, which was commissioned in 1981 [58].

A more cost-effective method of reducing sulfur dioxide emissions is to reject as much pyrrhotite as possible from the smelter feed by separating pyrrhotite from pentlandite in the concentrator. As much as 50 – 60 % of the pyrrhotite content of the ore is now rejected in the major Canadian nickel operations at Sudbury and Thompson. At Thompson, Inco reduced SO_2 emissions by 45 % between 1976 and 1986 simply by increasing pyrrhotite rejection, but incurred significant metallurgical penalties by doing so [25]. Not only was the overall recovery of nickel reduced but the absence of much of the pyrrhotite removed a major energy source for the smelting process. Since the roasting and converting steps were designed to be autogenous using the iron sulfide as fuel, when over 50 % of the pyrrhotite is rejected prior to smelting insufficient iron is available to sustain the converting operation, and extra fuel must be supplied.

Maximum pyrrhotite rejection is practiced by both Inco and Falconbridge at their Sudbury operations. In these ores the nickel content of the pyrrhotite mineral is higher than in the Thompson ore and so pyrrhotite rejection results in significant losses in nickel recovery. A process to treat pyrrhotite concentrate separately to recover nickel, iron ore, and sulfuric acid, was operated by Inco for many years but the operation was abandoned in the mid 1980s when it became uneconomic due to increasingly stringent sulfur emission limits [32].

Falconbridge rejects over 55 % of the pyrrhotite in its ore and recovers sulfuric acid from the sulfur dioxide in the fluidized-bed roaster off-gas stream. Electric furnace and converter off-gases are vented to the atmosphere as a low-strength sulfur dioxide stream. The distribution of sulfur in the Falconbridge operation in 1983 is detailed in Table 8 [24], [52].

Table 8. Sulfur distribution at Falconbridge, Sudbury, Ontario in 1983 [24]

	Sulfur, t/d	Distribution, %
Mill tailings, incl. pyrrhotite	540	58.5
Smelter slag	11	1.2
Nickel – copper matte	44	4.8
Sulfuric acid production	200	21.7
Stack emissions	104	11.3
Copper concentrate, etc.	23	2.5

Particulate emissions from the Falconbridge smelter were also reduced by 80 % when the fluidized-bed roasting – electric furnace process replaced the old sintering – blast furnace process in 1978.

The Outokumpu flash smelting process is probably the most environmentally compatible of the current commercial nickel smelting processes because it permits the capture of virtually all the sulfur dioxide produced prior to the conversion step. The recovery of sulfur dioxide from the off-gas stream from Peirce – Smith converters is not generally feasible due to the low sulfur content of the off-gas and intermittent nature of the operation.

New Developments in Nickel Smelting In contrast to the copper industry, in which a number of continuous smelting processes have been commercialized, there has been little interest in developing a process for nickel concentrates in which the primary smelting and converting steps are combined into a single continuous operation. One such process was proposed by QUENEAU and SCHUMANN in 1976 but has not been adopted commercially [59].

The major development in nickel smelting during the 1990s will be the modernization of Inco's aging nickel – copper smelter at Copper Cliff, Ontario. Ontario Government regulatory measures to reduce acid rain require that Inco reduce its emissions of sulfur dioxide from 685×10^3 t/a in 1990 to 265×10^3 t/a by 1994, corresponding to an increase in the fixation of the sulfur in

the ore from 70 % to 90 %. In the existing operation, 55 % of the sulfur is rejected to tailings as pyrrhotite, and a further 15 % is converted either to acid or to liquid sulfur dioxide. The remaining 30 % is emitted to the environment as low sulfur dioxide content off-gases from the Herreschoff roasters, reverberatory furnaces, and the nickel matte and copper converters.

Several potential smelting options were examined by Inco, including the roast-reduction – smelting process, which was tested on a plant scale at Thompson in 1979 [32], and the oxygen flash smelting of nickel concentrate, which was tested with the copper flash furnace at Copper Cliff in 1976 [60]. However, none of these options was acceptable since they did not eliminate the copper converting operation, which itself produces more than the 1994 sulfur dioxide emission limit of 265 000 t/a [61].

The strategy eventually selected for the modernization is based on the oxygen flash smelting of bulk nickel – copper concentrate followed by converting the high-grade furnace matte in the existing nickel converters. The converter matte will be separated into metallics, nickel sulfide, and copper sulfide fractions using the existing matte separation process, and the iron-free copper sulfide (Cu_2S) will be oxygen flash smelted to semiblister copper. In this way the weak gas streams from the roasters, reverberatory furnaces, and copper converters will be totally eliminated, and the volume of gases from the nickel converters will be halved. All the sulfur dioxide in the high-strength (80 % SO_2) off-gas streams from the flash furnaces will be fixed as sulfuric acid or liquid sulfur dioxide. The oxygen flash smelting process is very energy efficient, and energy consumption in the smelter will be halved.

Since the entire nickel – copper separation will in future be carried out in the matte separation plant, Inco's milling operations will be simplified. Operations will be consolidated in the Clarabelle mill, and the Copper Cliff and Frood – Stobie mills will be closed. The function of the modernized Clarabelle mill will be to reject pyrrhotite and produce a bulk nickel – copper concentrate. A large new semiautogenous grinding mill and new flotation cells, more than ten times larger than the existing cells, will be installed. These changes are projected to increase the rejection of sulfur from the ore as pyrrhotite to tailings to 67 % [61].

In the smelter, two large new flash smelting furnaces, each capable of treating 1800 t/d of bulk concentrate, and a smaller flash furnace capable of treating 725 t/d of Cu_2S concentrate, will be constructed. A new oxygen plant will produce 450 t/d to supplement the 1300 t/d currently available.

A new sulfuric acid plant with a design rate of 2300 t/d will handle the off-gas from both large flash furnaces. Off-gas from the copper flash furnace will form the feed to the existing liquid sulfur dioxide plant. Installation of the new acid plant will permit the closing of the roaster operation and acid plant at the iron ore recovery plant.

The first large flash furnace together with the new oxygen plant and acid plant are scheduled for completion in 1992, while the second large flash furnace will be operating by the end of 1993.

4.4. Treatment of Converter Matte

Nickel – copper converter matte is essentially a melt of nickel, copper, and sulfur with small amounts of cobalt, iron, and oxygen, and traces of the noble metals and various undesirable impurities, including selenium, tellurium, and entrained slag. In the South African platinum industry, where nickel – copper mattes containing over 1000 g/t platinum group metals are common, the noble metal content of the matte far exceeds the base metal content in value. The platinum group metal contents of the Sudbury mattes, although much lower than in the South African mattes, are still of major economic significance.

Further processing of nickel – copper converter mattes is carried out to separate and recover nickel, copper, cobalt, and the noble metals. Mattes may be treated by hydrometallurgy (the Sherritt, Outokumpu, and Falconbridge leach processes), by electrometallurgy if they are low in copper (Inco's direct electrorefining of matte anodes), or by pyrometallurgy (Inco's slow-cooling matte separation process).

4.4.1. *Inco Matte Separation Process [1]*

The controlled slow-cooling matte separation process was developed by Inco in the 1940s to replace the obsolete Orford Process which depended on the different solubilities of copper and nickel sulfides in molten sodium sulfide. Other operations which had used the Orford Process, Rustenburg Platinum in the Republic of South Africa and the major Soviet nickel producers, have subsequently adopted the slow-cooling technique.

This process is based on the fact that when molten nickel – copper mattes freeze slowly, the constituents segregate into grains that are separate and distinct chemical phases. The major phases are Cu_2S and Ni_3S_2, but if the matte contains less sulfur than is required to form these compounds, the excess nickel forms a magnetic alloy phase with copper, which also preferentially collects the noble metals. The slow-cooled matte can then be comminuted and separated into nickel sulfide, copper sulfide, and nickel – copper alloy fractions by normal mineral beneficiation techniques. The nickel – copper alloy, which is separated magnetically, contains virtually all the platinum group metal and gold values at a substantially increased grade compared to the converter matte.

In the Inco matte separation plant at Copper Cliff (Fig. 6) [34] molten sulfur-deficient converter matte (50 % Ni, 26 % Cu, 0.5 % Fe, 22 % S) is poured into molds at 1000 °C and cooled slowly over a period of four days to about 200 °C. The solid matte is crushed and ground and is then separated into its components by magnetic separation and flotation. The copper sulfide concentrate (73 % Cu, 5 % Ni), which also contains most of the silver, selenium, and tellurium, is converted to blister copper in Inco's copper smelting circuit. The silver, selenium, and tellurium are recovered from the copper refinery anode slimes. The magnetic nickel – copper alloy (65 % Ni, 20 % Cu) forms the major feedstock to Inco's Copper Cliff nickel refinery, where the nickel is refined by the pressure carbonyl process to high-grade nickel powder and pellets, and copper and the precious metals are recovered from the refining residue. The nickel sulfide concentrate (70 % Ni, 0.6 % Cu), which is essentially depleted in precious metals, forms the feed to the fluidized-bed roasting plant.

Figure 6. Flow sheet of the Inco matte separation process

a) Converter matte from Copper Cliff smelter; b) Rod mill; c) Ball mill; d) Magnetic separator; e) Centrifuge; f) Rake classifier; g) Flotation cell; h) Thickener; i) Disc filter; j) Dryer

The three large sulfide nickel operations in the former Soviet Union at Pechenga, Monchegorsk, and Norilsk, all use similar slow-cooling matte separation processes, producing separate nickel and copper sulfide concentrates. Rustenburg Platinum in the Republic of South Africa uses the slow-cooling technique to separate a magnetic nickel – copper alloy with a high noble-metal content for processing to recover and refine the platinum group metals, but does not separate the nickel and copper sulfides. The bulk nickel – copper concentrate is treated by pressure hydrometallurgy to separate the nickel and copper.

4.4.2. *Fluidized-Bed Roasting of Nickel Sulfide [62]*

Nickel sulfide concentrates are roasted in fluidized-bed roasters to produce nickel oxide at Inco's matte treatment plant in Copper Cliff and at the major nickel operations in the former Soviet Union. The dead roasting of finely ground nickel sulfide concentrates in a fluidized-bed roaster presents difficulties because nickel sulfide softens and becomes sticky at about 650 ° C, while sulfur removal must be carried out at a temperature above 1100 °C, at which the sulfide is molten, to achieve the required degree of sulfur elimination at an economic rate. A further problem is the very fine nature of the concentrates. Typically 99 % of the particles are less than 75 µm, with about 20 % in the 10 µm range. It is therefore difficult to feed such fine material into a fluidized-bed roaster without either incurring excessive dust carryover from the bed, or causing the bed to fuse with consequent loss of fluidization.

In Inco's practice (Fig. 7) [34] the concentrate is pelletized in order to provide enough mass to carry the sulfide particles down through the rising gas stream into the bed. Agglomeration is carried out by adding recovered roaster dust (about 10 % of the total) to the nickel sulfide concentrate slurry received from the matte flotation circuit. The green nickel sulfide pellets are charged into four fluidized-bed roasters which operate under optimum conditions at a superficial gas velocity of about 2 m/s with a bed expansion of about 150 %. The average retention time of a particle in the bed is ca. 8 h. Roasting under these conditions is autogenous at 1100 °C, but the roaster air is enriched with oxygen to increase the elimination of sulfur and increase the concentrate throughput rate. A coarse granular nickel oxide (NiO) containing ca. 0.2 % S is drawn off from the bed overflow. A single roaster can treat ca. 350 t/d of nickel concentrate.

Figure 7. Flow sheet of the Inco nickel matte roasting process

a) Disc filter; b) Pelletizing disc; c) Electrostatic precipitator; d) Cyclone; e) Roaster; f) Reroaster; g) Cooler; h) Chlorination reactor; i) Splash tower; j) Packed tower

The roaster calcine is either cooled in a fluidized cooler with water sprays from 1100 °C to 90 °C and shipped to one of Inco's nickel refineries (Copper Cliff or Port Colborne, Ontario; or Clydach, Wales), or is further desulfurized in a second fluidized-bed roaster. In this second roasting step the sulfur content is reduced to levels as low as 0.005 %. This material is either marketed directly as ‘Sinter 75' (75 % Ni, 0.7 % Cu, and 0.006 % S), which is used in alloy steel making, or is treated by chlorination and reduction to lower its copper content. The removal of copper and other impurities is carried out by the injection of chlorine gas into a fluidized-bed reactor at 1200 °C, at a chlorine addition rate of about 3 wt % of the reactor feed. The bed is heated by light fuel oil and oxygen-enriched air. The reactor product typically contains 0.3 % Cu and less than 0.01 % S. It was formerly treated with a gas containing 75 % hydrogen at 510 °C in another fluidized-bed reactor to yield Incomet, a metallic nickel product, which, however, is no longer made.

[Top of Page]

5. Hydrometallurgy of Nickel Concentrates and Mattes [63]

Several hydrometallurgical processes are in commercial operation for the treatment of nickel – copper mattes to produce separate nickel and copper products. In addition, the hydrometallurgical process developed by Sherritt Gordon in the early 1950s for the direct treatment of nickel sulfide concentrates, as an alternative to smelting, is still commercially viable and competitive, despite very significant improvements in the economics and energy efficiency of nickel smelting technology [64].

In a typical hydrometallurgical process, the concentrate or matte is first leached in a sulfate or chloride solution to dissolve nickel, cobalt, and some of the copper, while the sulfide is oxidized to insoluble elemental sulfur or soluble sulfate. Frequently, leaching is carried out in a two-stage countercurrent system so that the matte can be used to partially purify the solution, for example, by precipitating copper by cementation. In this way a nickel – copper matte can be treated in a two-stage leach process to produce a copper-free nickel sulfate or nickel chloride solution, and a leach residue enriched in copper. The copper-rich residue is treated by pressure leaching, or by roasting and leaching, to solubilize the copper as copper sulfate so that it can be recovered from solution electrolytically as cathode copper. Nickel is recovered from the purified nickel sulfate or chloride solution either electrolytically as a pure nickel cathode or by chemical reduction with hydrogen to give pure nickel powder.

The range of compositions for mattes treated by hydrometallurgical processes is shown in Table 9 [63]. The nickel contents of the mattes treated hydrometallurgically are in the range 35 – 75 %, while the copper content varies from 0 to 52 %, and sulfur from 6 to 24 %. Low-copper mattes (< 10 % Cu) can be treated by ammoniacal pressure leaching, by ferric chloride leaching, or by direct electrorefining of the matte. High-copper mattes can be treated by high-pressure or atmospheric pressure sulfuric acid leaching or hydrochloric acid leaching.

Table 9. Hydrometallurgical nickel refineries [63]

Company/operation	Capacity, t/a Ni	Feed composition, %				
		Ni	Cu	Co	Fe	S
Falconbridge, Norway	54 000	35 – 40	30 – 35	1.0	2.5	22 – 24
Inco, Thompson	46 000	73	3	0.8	0.6	20
Western Mining	33 000	44 – 72	3 – 5	0.8	1 – 25	20 – 23
Sherritt Gordon	24 000	15 – 70	1 – 5	0.5	2 – 30	18 – 30
Sumitomo, Niihama	22 000	72	5	0.7	0.5	21
Rustenburg Refiners	20 000	47	27	0.5	3.0	21
Outokumpu, Harjavalta	17 000	55 – 65	25 – 35	0.6	0.2	6
SLN, Le Havre	16 000	75		1.5	2.5	20
Jianchuan, China	15 000	68	7	1.0	2.0	21
Bindura, Zimbabwe	14 400	66	25	0.6	0.2	6
Empress, Zimbabwe	5000	40	52	0.2	0.2	6
Western Platinum	2000	48	28	0.5	1.0	21

The sulfur contents of the mattes are adjusted during the conversion process in the smelter to the optimal level for the subsequent leaching process. Sulfur levels are typically 20 – 23 %, except when the matte is to be treated by the Outokumpu atmospheric pressure sulfuric acid leaching process, for which the sulfur content is reduced to about 6 %.

5.1. Ammonia Pressure Leaching [1], [65]

The first successful commercialization of a hydrometallurgical process for the treatment of a nickel sulfide concentrate was realized by Sherritt Gordon Mines at Fort Saskatchewan, Alberta, Canada in 1954. This process was developed specifically to treat a pentlandite concentrate from Sherritt's Lynn Lake mine in northern Manitoba by ammonia pressure leaching. The original plant was designed to produce 8000 t/a of nickel powder and briquettes by the chemical reduction of nickel in ammoniacal solution with hydrogen at high pressure. The same plant, with only minor process and equipment modifications, can now refine 24 000 t/a of nickel from a wide range of feed materials, including pentlandite concentrates, low-copper nickel mattes, and nickel sulfates and carbonates. The ammonia pressure leach process is also operated by Western Mining at Kwinana, Western Australia. Originally, this refinery processed nickel sulfide concentrates, but now treats a blend of converter and flash furnace nickel mattes to produce powder and briquettes at a rate of 33 000 t/a Ni. A block flow diagram of the ammonia pressure leach process as operated by Sherritt Gordon is shown in Figure 8.

Figure 8. Flow sheet of the Sherritt ammonia pressure leach process

The finely ground nickel sulfide concentrates and mattes are leached in ammoniacal ammonium sulfate solution at 80 – 95 °C under 850 kPa air pressure in a two-stage countercurrent process in eight four-compartment horizontal autoclaves (Fig. 9). Nickel, cobalt, and copper are dissolved as soluble ammonia complexes, while sulfide is oxidized to form a series of soluble thio salts. Reactive iron is oxidized and reports to the leach residue as a hydrated oxide together with pyrite which does not react in the leach:

Figure 9. Cutaway view of a horizontal leaching autoclave

$$NiS \cdot FeS + 3\,FeS + 7\,O_2 + 10\,NH_3 + 4\,H_2O \rightarrow Ni(NH_3)_6SO_4 + 2\,Fe_2O_3 \cdot H_2O + 2\,(NH_4)_2S_2O_3$$

The leach solution typically contains 50 – 60 g/L Ni, 1 – 2 g/L Co, 5 – 10 g/L Cu, 130 g/L NH_3 and varying amounts of thio salts, including thiosulfate and thionates, as well as ammonium sulfamate ($H_2NSO_3NH_4$), which is formed by the reaction of

thionate with oxygen and ammonia.

The leach solution is boiled to distil off the free ammonia, and elemental sulfur and sulfur dioxide are added to augment the thio salts in precipitating copper as copper(II) sulfide:

$$Cu(NH_3)_4SO_4 + S + SO_2 + 2\,H_2O \rightarrow CuS + 2\,(NH_4)_2SO_4$$

The copper sulfide is sold to a copper smelter. The ammonia to nickel molar ratio is adjusted to 2 : 1 and the copper free ammoniacal nickel sulfate solution is oxidized at 235 °C under 4 MPa air pressure to convert the sulfur compounds to sulfate and to hydrolyze the sulfamate ion to sulfate. If these sulfur compounds were not fully converted to sulfate, the nickel powder product would contain unacceptably high levels of sulfur.

In the final step of the process, nickel is precipitated from solution as a metal powder by reduction with hydrogen under 3.6 MPa pressure at 200 °C in a four-agitator horizontal autoclave:

$$[Ni(H_2O)_4(NH_3)_2]SO_4 + H_2 \rightarrow Ni + (NH_4)_2SO_4 + 4\,H_2O$$

Details of the reduction technique are given in Section Hydrogen Reduction to Nickel Powder . The nickel powder is either compacted into briquettes for use in stainless steel production or is rolled into nickel strip for coinage production.

Under the specified process conditions cobalt is not precipitated during nickel reduction and the reduction end solution contains 1 – 2 g/L each of nickel and cobalt as well as about 400 g/L ammonium sulfate. This solution is treated with hydrogen sulfide to precipitate the nickel and cobalt as a mixed metal sulfide intermediate product, leaving a pure ammonium sulfate solution which is evaporated to crystallize ammonium sulfate for sale as a fertilizer.

The mixed metal sulfides produced in both the Sherritt and the Western Mining nickel refineries are processed in Sherritt's cobalt refinery in Canada [65]. The sulfides are pressure leached in sulfuric acid under 1.15 MPa air pressure at 150 °C in a lead- and brick-lined, six-compartment horizontal autoclave to form a solution of nickel and cobalt sulfates:

$$NiS + CoS + 4\,O_2 \rightarrow NiSO_4 + CoSO_4$$

Iron is removed from solution in a second autoclave by adjusting the pH to 2.5 with aqueous ammonia solution. At this stage the solution typically contains 40 g/L Ni, 30 g/L Co, and less than 10 mg/L Cu and Fe. The solution is then treated with aqueous ammonia solution under air pressure to oxidize the cobalt(II) ion to the cobalt(III) state which is stable as the soluble cobalt(III) pentammine complex ion $[Co(NH_3)_5 \cdot H_2O]^{3+}$. Nickel is removed in a two-stage process by adding sulfuric acid to selectively precipitate nickel(II) ammonium sulfate, which is recycled to the nickel refinery. The cobalt/nickel ratio in the purified solution is typically 3000 : 1.

The cobalt(III) ion is reduced to cobalt(II) by treating the purified solution with cobalt powder and sulfuric acid. Cobalt powder is precipitated from solution by reduction with hydrogen at 180 °C and 4.3 MPa.

The pentammine cobalt refining process has also been operated by Outokumpu at Kokkola in Finland since 1968.

5.2. Atmospheric Acid Leaching

The atmospheric acid leach process for the treatment of high-copper, low-sulfur nickel matte was developed by Outokumpu [1] in 1960 to process material from its nickel mine in Finland, and was later adopted by the Bindura and Empress nickel refineries in Zimbabwe [66]. In this process the leaching operations are carried out in trains of air-agitated pachuca tanks, in contrast to the mechanically-agitated horizontal autoclaves used in the pressure leaching process.

The Outokumpu process is outlined in Figure 10. Granulated matte, typically analyzing 55 – 65 % Ni, 25 – 35 % Cu, 0.6 % Co, 0.2 % Fe, and 6 % S, is ground to 90 % less than 54 µm and leached at 80 °C in acidic sulfate solution in a three-stage countercurrent leach circuit. Nickel, which is largely present in the low-sulfur matte as metallic nickel, dissolves in the first stage leach by reaction with sulfuric acid and with soluble copper, which is cemented from solution as copper metal. Copper sulfide in the matte does not react:

Figure 10. Flow sheet of the Outokumpu atmospheric acid leach process

$$Ni + H_2SO_4 + 1/2\,O_2 \rightarrow NiSO_4 + H_2O$$

$$Ni + CuSO_4 \rightarrow NiSO_4 + Cu$$

Most of the remaining nickel and some of the copper is leached in the second and third leach stages, which operate under increasingly oxidizing and acidic conditions. The solution from the first leach stage is a copper-free nickel sulfate solution, while the residue from the third stage is enriched in copper relative to nickel. Metal extractions in the atmospheric leach are typically about 90 % Ni and 50 % Cu.

The atmospheric leach residue, which contains about 15 % Ni, 50 % Cu, and 20 % S, was originally recycled to the Outokumpu nickel smelter to recover the metal values. This residue is now treated in a fourth stage, a pressure leach under mildly oxidizing conditions at 160 °C, in which the nickel is extracted selectively, leaving a low-nickel, high-copper sulfide residue that can be treated directly in the copper smelter [67].

The Bindura and Empress refineries do not have a pressure leaching step and operate in the original Outokumpu mode, with copper recovery by electrowinning from the second-stage leach liquor, and recycle of the leach residue to a nickel smelter. At the Empress refinery, good quality copper cathode is produced, despite an unfavorable copper to nickel ratio in the solution, by using air-sparged cells at relatively low current density [66].

The first stage atmospheric leach step is primarily a solution purification step designed to produce a copper-free nickel sulfate solution. Air addition rates are reduced in the later pachuca leach tanks in the first stage to avoid redissolution of copper, and the pH is allowed to rise to 6.0 to ensure precipitation of iron by hydrolysis. Lead is precipitated by adding barium hydroxide or carbonate to the solution, either in the first stage leach or in a separate process step, to precipitate lead sulfate, which coprecipitates with barium sulfate. Cobalt is separated from the nickel sulfate solution in a later step, in which a slurry of nickel(III) hydroxide is added to precipitate cobalt as cobalt(III) hydroxide:

$$Ni(OH)_3 + CoSO_4 \rightarrow NiSO_4 + Co(OH)_3$$

The nickel(III) hydroxide is produced by electrolytic oxidation of nickel(II) hydroxide, formed by neutralizing purified nickel sulfate solution with sodium hydroxide. The cobalt(III) hydroxide precipitate is refined to cobalt metal and cobalt salts by the pentammine process at Outokumpu's cobalt refinery at Kokkola, Finland.

Nickel is recovered from the purified nickel sulfate solution, which contains about 75 g/L Ni, as a high-grade cathode by direct electrowinning (see Section Electrowinning). Anolyte solution containing about 50 g/L Ni and 50 g/L H_2SO_4, is recycled for use as a leachant in the leaching circuits.

5.3. Acid Pressure Leaching

The acid pressure leaching process for the treatment of high-copper nickel mattes was developed by Sherritt Gordon during the 1960s and is currently operated by all four platinum producers in the Republic of South Africa: Rustenburg Refiners, Impala Platinum, Western Platinum, and Barplats [68], [69]. A similar process was also operated by the Amax nickel refinery in Louisiana, United States, from 1974 to 1986 [70], [71].

Acid pressure leaching is normally carried out in brick- and lead-lined horizontal multicompartment autoclaves at 135 – 160 °C and oxygen partial pressures of 140 – 350 kPa. The major advantage of this process for the platinum producers is that very high extractions of nickel, copper, and sulfur can be achieved. Typically, the metal and sulfur extractions are greater than 99.9 %, so that the leach residue is a high-grade platinum group metal concentrate that is virtually free from nickel, copper, and sulfur and can be treated directly in a platinum refinery. An upgrading factor for the platinum group metals of over 100 from the matte to the leach residue is readily attainable [69].

The process flows heet differs significantly for the various operations. Rustenburg and Impala use two countercurrent stages of continuous pressure leaching at 135 – 150 °C, while the smaller Western Platinum and Barplats refineries operate an atmospheric leach at 85 °C followed by a single-stage continuous pressure leach at 160 °C. The nickel products also differ widely. Rustenburg Refiners recover nickel as a high-purity cathode by direct electrowinning, whereas Impala produces nickel powder and briquettes by hydrogen reduction, and Western Platinum and Barplats produce crystalline nickel sulfate, which is processed to metal or plating salts elsewhere.

The Impala Platinum flow sheet [72] is outlined in Figure 11. The nickel – copper matte is leached in two stages at 135 °C under 1 MPa air pressure in spent copper electrolyte solution.

Figure 11. Flow sheet of Impala Platinum acid pressure leach process

$$Ni_3S_2 + H_2SO_4 + 1/2\,O_2 \rightarrow NiSO_4 + 2\,NiS + H_2O$$

$$2\,NiS + 4\,O_2 \rightarrow 2\,NiSO_4$$

$$NiS + CuSO_4 \rightarrow NiSO_4 + CuS$$

Solution from the first stage leach, which contains a high concentration of nickel (typically 100 g/L Ni) and low levels of copper and iron, is contacted with nickel powder and sodium hydrosulfide to precipitate copper, and iron is then removed as an ammonium jarosite precipitate using a horizontal multicompartment autoclave operating at 150 °C:

$$CuSO_4 + Ni \rightarrow NiSO_4 + Cu$$

$$3\,Fe_2(SO_4)_3 + (NH_4)_2SO_4 + 12\,H_2O \rightarrow 2\,NH_4Fe_3(SO_4)_2(OH)_6 + 6\,H_2SO_4$$

The jarosite precipitation step also effectively removes lead and arsenic from the nickel sulfate solution. The purified nickel

sulfate solution is adjusted with aqueous ammonia solution to form the nickel(II) diammine complex ion, and nickel is recovered as a powder by reduction with hydrogen under pressure:

$$Ni(NH_3)_2SO_4 + H_2 \rightarrow Ni + (NH_4)_2SO_4$$

Cobalt and residual nickel are recovered from the reduction end solution as the nickel sulfate – cobalt sulfate – ammonium sulfate double salts, which are refined to produce cobalt metal powder by the Sherritt pentammine process and hydrogen reduction.

The residue from the first stage leach is leached under more oxidizing and more acidic conditions in copper spent electrolyte in the second-stage pressure leach, which completes the extraction of nickel and copper sulfides:

$$NiS + 2\,O_2 \rightarrow NiSO_4$$

$$Cu_2S + 1/2\,O_2 + H_2SO_4 \rightarrow CuS + CuSO_4 + H_2O$$

$$CuS + 2\,O_2 \rightarrow CuSO_4$$

The solution from the second-stage pressure leach, which contains both nickel and copper sulfate with traces of iron and selenium, is treated with sulfur dioxide to precipitate selenium as copper(I) selenide, and copper is recovered as cathode by electrowinning. The spent electrolyte, which contains high levels of nickel as well as 20 g/L Cu and 50 – 70 g/L H_2SO_4, is recycled to the pressure leach circuits.

The second-stage leach residue contains the platinum group metals, with only minor levels of nickel, copper, and sulfur.

5.4. Chloride Leach Processes

Nickel matte refining processes based on leaching in chloride solution in the presence of chlorine gas have been developed and successfully commercialized by Falconbridge at Kristiansand in Norway [73] and by Societé Le Nickel (SLN) at Le Havre-Sandouville in France [74]. Leaching of the matte is carried out at atmospheric pressure at the boiling point of the leach solution (ca. 110 °C). Chlorine, which is recovered from the electrolysis cells, is sparged directly into the leach tanks. In the SLN process the leachant is the iron(III) chloride solution recovered from an iron removal step, whereas in the Falconbridge process the leachant is a solution of copper and nickel chlorides recycled from the copper residue treatment circuit. The flow sheet of the Falconbridge process is shown in Figure 12.

Figure 12. Flow sheet of the Falconbridge refinery process

Granulated nickel – copper mattes from the Falconbridge smelter in Ontario, Canada and from BCL in Botswana, with an average composition of 40 – 45 % Ni, 25 – 30 % Cu, 20 – 22 % S, 2 – 3 % Fe, and 1 – 1.5 % Co, are ground in a ball mill [73]. The ground matte is leached with chlorine in a nickel – copper chloride solution in a train of agitated tanks. The leaching conditions are controlled by means of redox potential measurements to ensure selective leaching of nickel:

$$2\,CuCl + Cl_2 \rightarrow 2\,CuCl_2$$

$$Ni_3S_2 + 2\,CuCl_2 \rightarrow 2\,NiS + NiCl_2 + 2\,CuCl$$

$$NiS + 2\,CuCl_2 \rightarrow NiCl_2 + 2\,CuCl + S$$

$$Cu_2S + S \rightarrow 2\,CuS$$

Essentially all the copper and sulfur present in the matte remain in the leach residue as CuS. The leach residue still contains about 8 % Ni as unreacted NiS, and the leach solution still contains high concentrations of copper. The leach slurry is therefore heated to 140 – 145 °C in two vertical autoclaves, connected in series, to promote the precipitation of copper and the dissolution of nickel by a series of metathesis reactions:

$$Ni_3S_2 + S + 2\,CuCl \rightarrow Cu_2S + NiCl_2 + 2\,NiS$$

$$Ni + S + 2\,CuCl \rightarrow NiCl_2 + Cu_2S$$

$$Cu_2S + S \rightarrow 2\,CuS$$

$$S + 2\,CuCl \rightarrow CuS + CuCl_2$$

The discharge from the autoclaves, which still contains about 7 g/L Cu in solution, is treated with fresh matte to reduce the copper concentration to less than 0.5 g/L. Overall nickel extraction is about 90 %, and the final residue contains 6 – 8 % Ni.

Iron, which is largely dissolved in the chlorine leach, is precipitated by oxidation with chlorine and hydrolysis with nickel carbonate. Cobalt is extracted from the nickel chloride solution by solvent extraction with triisooctylamine (TIOA) and, after purification of the strip solution, is recovered as high-purity cathode by electrowinning. The nickel chloride raffinate is diluted and purified further by treatment with chlorine and nickel carbonate to remove the remaining traces of cobalt, iron, copper, arsenic, lead, and manganese. High-purity nickel is recovered by direct electrowinning as cathode, and as crowns by direct plating onto a suitably masked blank.

Copper is extracted from the chlorine leach residue by roasting it in a fluidized-bed roaster to convert the copper sulfide and elemental sulfur to copper oxide and sulfur dioxide, which is converted to sulfuric acid, and leaching the calcine in sulfuric acid to selectively leach the copper. The copper is recovered from the sulfate solution by conventional electrowinning.

The calcine leach residue, which contains 50 % Ni and 18 % Cu as well as the platinum group metals (PGM), undergoes further chloride leaching to recover the nickel and copper in solution for recycling to the leach circuit, leaving the platinum group metals in an upgraded concentrate. Typical process stream compositions for the Falconbridge operation are shown in Table 10.

Table 10. Process data for the Falconbridge chlorine leach process [73]

Stream	Ni	Co	Cu	Fe	S	Cl
Matte, %	45	1	28	2	22	
Feed solution, g/L	60		25	1		90
Sulfide leach residue, %	7	0.5	56	2	33	0.3
Pregnant solution, g/L	230	5	0.5	6		270
Ni electrolyte, g/L	60					60
Roaster calcine, %	9	0.5	63	2	0.5	
Cu electrolyte, g/L	60	6	60	2.5		
PGM concentrate, %	20	1	25	5	15	5

In the SLN process, in which the feed matte produced from laterite ore in New Caledonia contains virtually no copper, the pregnant leach liquor contains 200 g/L Ni with 5 g/L Co and 10 g/L Fe. Iron is removed as ferric chloride by solvent extraction with tributyl phosphate (TBP). Part of the ferric chloride strip solution is recycled to the chlorine leach, while the balance is concentrated and sold. Cobalt chloride is extracted with TIOA and sold as solution for cobalt recovery elsewhere. Nickel is recovered from the purified solution as high-purity cathode by electrowinning [74].

5.5. Treatment of Nickeliferous Pyrrhotite [1]

Large tonnages of pyrrhotite concentrates containing up to 1 % Ni are currently rejected in the milling and concentrating operations of the major Canadian nickel producers as a means of reducing the iron and sulfur inputs to their smelters, and hence reducing sulfur dioxide emissions. These pyrrhotite concentrates represent a major potential source of nickel and several attempts have been made to develop economically viable processes to exploit them. The primary requirement for a pyrrhotite treatment process is that it should produce an iron ore suitable for use in the steel industry and yield a good recovery of nickel. Such processes are typically based on roasting to eliminate all or part of the sulfur and hydrometallurgical treatment of the calcine to recover the nickel.

In 1956 Inco commissioned a plant at Copper Cliff, Ontario, to treat 1.2×10^6 t/a of pyrrhotite concentrate analyzing 0.9 % Ni, 58 % Fe, and 35 % S. The iron sulfide concentrate was first oxidized to a low-sulfur calcine in fluidized-bed roasters, producing an off-gas containing sulfur dioxide from which sulfuric acid was produced. The calcine was then passed through a reducing kiln to reduce the nickel, cobalt, and copper oxides selectively to metallic form, so that they could be dissolved selectively in ammoniacal ammonium carbonate solution. The solution was purified to remove copper as the sulfide and nickel was precipitated as a basic nickel carbonate. The basic carbonate was calcined to a marketable oxide product containing 77 % Ni. The leached iron oxide residue was pelletized and indurated for market. This plant operated until the early 1980s, when marginal economics and increasing constraints on sulfur emissions resulted in its closure.

From 1960 until the early 1970s, Falconbridge operated a process in which pyrrhotite concentrate, analyzing 1.1 % Ni, 57 % Fe, and 36 % S, was sulfation roasted at 680 °C to convert the nickel, copper, and cobalt to their water-soluble sulfates. The calcine was then water-leached to extract the metals, and nickel, cobalt, and copper were precipitated from solution by cementation on iron turnings for recycling to the smelter. The iron oxide product analyzed 66 % Fe, 0.13 % Ni, and 0.5 % S.

[Top of Page]

6. Nickel Refining [1], [63]

Nickel differs from copper in that it is largely used as an alloying element in stainless steel and alloy steel production. Thus, whereas most copper is used in electrical and thermal energy applications, which require a highly refined metal, a high-purity metal is not required for many of nickel's most important markets. Nickel products such as nickel oxide, metallized nickel oxide, and ferronickel, which are designated Class II products, are produced directly by smelting and roasting and are sufficiently pure, without refining, for many nickel applications such as stainless steel production. These Class II products may contain significant levels of cobalt and copper and a range of trace impurities.

In other applications, high-purity nickel is essential and Class I nickel products, which include electrolytic cathode, carbonyl powder, and hydrogen-reduced powder, are made by a variety of refining processes. In general nickel is refined to decrease to an acceptable level only those impurities which would have an adverse effect on subsequent processing or on the properties of the refined metal product. These elements include antimony, arsenic, bismuth, cobalt, copper, iron, lead, phosphorus, sulfur, tin, and zinc. Cobalt, which resembles nickel closely in physical and chemical properties, is difficult to remove completely and since it is not often a serious contaminant in most applications for nickel, many Class I products contain quite high levels of cobalt.

The object of the refining process is not only to remove the impurities from the nickel, but also to recover those that have an economic value. Obvious examples are the precious and platinum group metals (Pt, Pd, Os, Rh, Ir, and Ru), cobalt, and copper; sulfur, selenium, and tellurium can sometimes also be recovered economically.

Historically the first successful nickel refining operation was established by the Mond Nickel Company (later absorbed by Inco) at Clydach, Wales, in 1902, using the carbonyl refining process invented by MOND and LANGER in 1889. This refinery is still in operation using a modern version of the carbonyl process. A large refinery that uses a high-pressure version of the carbonyl process was established by Inco at Copper Cliff, Ontario in 1972 [75].

The first electrolytic nickel refinery, treating nickel metal anodes, was built by Hybinette in Kristiansand, Norway, in 1910, and this plant was acquired by Falconbridge in 1928. The Kristiansand Refinery was modernized in the late 1970s by replacing the Hybinette process with the present chlorine leach process [73]. Inco established its first nickel refinery in Canada at Port Colborne, Ontario, in 1926, using a version of the Hybinette refining process. This refinery operated until 1984. In 1989 the only electrolytic nickel in North America was produced by Inco's refinery at Thompson, Manitoba, which electrorefines matte anodes [76]. This process is also operated in Japan [77] and China. The electrorefining of nickel metal anodes, which is effectively obsolete in Western Europe and North America, is still practiced in the former Soviet Union [44].

Outokumpu, SLN, and Falconbridge in Europe and Bindura, Empress, and Rustenburg Refiners in Southern Africa all recover electrolytic nickel by direct electrowinning from purified solutions produced by the leaching of nickel or nickel – copper mattes. Sherritt Gordon in Canada, Western Mining in Australia, and Impala Platinum in the Republic of South Africa recover refined nickel powder from purified ammoniacal solution by reduction with hydrogen.

6.1. Electrorefining [1]

Nickel electrorefining is carried out in a tank house containing a large number of electrolytic cells, each filled with a mixed nickel sulfate – nickel chloride solution, and containing 30 – 40 anodes (slabs of metallic nickel or nickel matte), interspersed with cathodes that are thin sheets of pure nickel. The anodes and cathodes in each cell are connected electrically in parallel, and the cells are connected in series. When electrical current is passed through the cells the anodes dissolve, and pure nickel deposits on the cathodes. Cathodes and anodes are replaced periodically to maintain continuity of production.

Crude nickel anodes are made by reducing nickel oxide with coke at temperatures up to 1540 °C and casting the molten metal in molds. The pure nickel starting sheets are made in special electrolytic cells in which nickel is deposited onto permanent stainless steel or titanium cathode blanks, from which the thin sheet is stripped after 24 or 48 h of deposition. The sheets are fitted with suspension loops and placed in the production cells. The electrolytic cells are normally made of concrete and are lined with an acid-resistant membrane such as glass fiber reinforced plastic material.

Nickel refining can be carried out with pure sulfate, mixed sulfate – chloride, or pure chloride nickel electrolytes. In practice, the mixed sulfate – chloride system is normally used for the electrorefining of either nickel metal or nickel matte. Sulfate and chloride electrolytes are used in the nickel electrowinning processes. The sulfate – chloride electrolyte has two major advantages over the sulfate system, in having a higher conductivity which results in a lower cell voltage, and in permitting the use of chlorine for electrolyte purification.

6.1.1. *Refining of Nickel Metal Anodes*

In the refining of nickel metal anodes the principal reaction at the anode is the dissolution of nickel metal as nickel ions:

$$\mathrm{Ni(anode)} \rightarrow \mathrm{Ni^{2+}(soln)} + 2\,\mathrm{e^-(anode)}$$

The principal cathodic reaction is the reduction of nickel ions from solution:

$$\mathrm{Ni^{2+}(soln)} + 2\,\mathrm{e^-(cathode)} \rightarrow \mathrm{Ni(cathode)}$$

At the normal cell operating voltage (ca. 1.6 V for metal anodes) the principal impurities from the anode such as iron, cobalt, lead, arsenic, and copper go into solution with the nickel. Silver, gold, the platinum group metals, sulfur, selenium, and tellurium fall to the bottom of the cell as an insoluble slime. If the soluble impurities reach the cathode surface they will codeposit with the nickel. Consequently, to avoid contamination of the refined nickel cathodes, the impure anolyte solution is taken through a purification process. The purified solution is then returned to the cathode compartment of the cell, which is segregated from the anode by a porous diaphragm in the form of a bag or box enclosing the cathode. The purified solution is fed into the cathode compartment at a rate sufficient to maintain the rate of nickel deposition. The diaphragm cloth is tightly woven so that a hydrostatic head of solution builds up relative to the rest of the electrolyte. This hydrostatic head forces nickel-depleted electrolyte through the diaphragm, from the cathode compartment into the anolyte, at a rate sufficient to prevent the ingress of either anolyte itself, or impurity ions, by diffusion into the cathode compartment.

6.1.2. *Refining of Nickel Matte Anodes*

Nickel sulfide anodes can be electrorefined directly to pure nickel cathode without the intermediate process steps of roasting the sulfide to oxide and reducing the oxide to produce metallic nickel anodes. Nickel sulfide anodes can be cast directly from low-copper converter matte or from melted nickel sulfide concentrate produced by the matte separation process. Controlled

cooling is necessary to produce anodes with the required mechanical properties. The anodes consist essentially of Ni_3S_2 and nickel alloy, but can contain up to 3 % copper as Cu_2S and other impurities such as iron, cobalt, lead, zinc, arsenic, selenium, and platinum group metals. Control of the sulfur content of the anodes is important because at sulfur contents of less than 15 %, the metallic nickel alloy phase dissolves preferentially, leaving nickel sulfide in the slime. At sulfur contents above 15 % , the matte anodes corrode uniformly to yield a slime containing elemental sulfur.

The principal anodic reactions are the oxidation of sulfide to elemental sulfur with simultaneous release of metal ions to the solution and of electrons to the anode:

$$Ni_3S_2 \rightarrow 3\,Ni^{2+}(soln) + 2\,S(slime) + 6\,e^-(anode)$$

The cathodic reaction is the same as in the metal anode refining process:

$$Ni^{2+}(soln) + 2\,e^-(cathode) \rightarrow Ni(cathode)$$

The net cell reaction for the nickel sulfide phase is thus

$$Ni_3S_2 \rightarrow 3\,Ni + 2\,S$$

The metallic nickel phase dissolves electrolytically as in the refining of nickel metal anodes:

$$Ni(anode) \rightarrow Ni^{2+}(soln) + 2\,e^-(anode)$$

The actual cell voltage, including the potential drops across the contacts and through the electrolyte, is about 2.8 V for newly charged matte anodes. As the anodes corrode, the sludge, which consists mainly of elemental sulfur, forms a strongly adherent porous surface layer which causes an increase in volume and effectively doubles the bulk of the anode. As the sludge layer becomes thicker, the electrical resistance between the electrodes increases, and the cell voltage increases to about 4.0 V by the end of the anode cycle. The increase in cell resistance also results in increased heating of the electrolyte. The solution temperature rise in the cell increases from about 15 °C at the start of the anode cycle to about 25 °C at the end of the cycle.

The anode potential is sufficiently high that some water is decomposed:

$$2\,H_2O \rightarrow O_2 + 4\,H^+ + 4\,e^-$$

This unwanted reaction, together with the electrolytic dissolution of impurities from the anode, lowers the anode nickel dissolution efficiency so that nickel is removed from solution at the cathode faster than it dissolves at the anode. The imbalance is corrected during electrolyte purification by dissolving matte in the electrolyte to neutralize the free acid and replenish the nickel content.

Operation of the nickel matte refining cell is similar to that of the metal anode cell except that the anodes are enclosed in bags to collect the voluminous sludge. The anode spacing in the matte refining cell is greater than in the metal refining cell, to allow for the increase in volume of the matte anode as it corrodes.

6.1.3. *Solution Purification [1], [78]*

For the production of high-quality nickel cathode it is essential that the anolyte solution be purified before it is supplied to the cathode compartment. The purification methods used depend on the impurities present in the anode.

Copper is often removed by cementation with activated metallic nickel powder, causing copper ions to precipitate as metallic copper while metallic nickel dissolves:

$$Ni + CuSO_4 \rightarrow Cu + NiSO_4$$

Alternatively copper may be precipitated as the sulfide with hydrogen sulfide:

$$CuSO_4 + H_2S \rightarrow CuS + H_2SO_4$$

This procedure, which is used in the matte electrorefining process, also precipitates arsenic:

$$2\,H_3AsO_3 + 3\,H_2S \rightarrow As_2S_3 + 6\,H_2O$$

Careful control of the redox potential is necessary to ensure complete precipitation of copper and arsenic while minimizing the coprecipitation of nickel.

Iron is normally removed by treating the solution with chlorine and nickel carbonate to oxidize the iron to iron(III) and precipitate iron(III) hydroxide by hydrolysis:

$$Fe_2(SO_4)_3 + 6\,H_2O \rightarrow 2\,Fe(OH_3) + 3\,H_2SO_4$$

$$3\,NiCO_3 + 3\,H_2SO_4 \rightarrow 3\,NiSO_4 + 3\,H_2O + 3\,CO_2$$

Iron(III) hydroxide coprecipitates other impurities from the anolyte, particularly lead and arsenic. In the pure sulfate electrolyte systems, oxidation of iron is accomplished by using air instead of chlorine. Iron can be removed from pure chloride

electrolytes by solvent extraction with tributylphosphate.

Cobalt is precipitated as cobalt(III) hydroxide by treating the solution with chlorine or nickel(III) hydroxide to oxidize the cobalt (II) to cobalt(III). Nickel carbonate is added to control the pH.

$$2\,CoSO_4 + Cl_2 + 3\,NiCO_3 + 3\,H_2O \rightarrow 2\,Co(OH)_3 + 2\,NiSO_4 + NiCl_2 + 3\,CO_2$$

Most of the cobalt precipitates at pH 4 at an oxidation potential of + 1 V. Chlorine cannot be used in pure sulfate electrolyte, and in this system, nickel(III) hydroxide is normally used. Other oxidants which can be used to remove cobalt from the sulfate system include peroxide, persulfate, and ozone.

Cobalt is normally removed from pure chloride nickel electrolytes by solvent extraction with a tertiary amine such as triisooctylamine. Phosphine-based solvent extraction reagents such as di-2-ethylhexylphosphoric acid (D2EHPA) are used to extract cobalt from nickel sulfate solutions.

In practice the purified solutions used in nickel electrorefining are not simple mixtures of nickel sulfate and nickel chloride. The electrolyte is a weakly acidic aqueous solution of nickel, sulfate, sodium, and chloride ions, and boric acid. The sodium and chloride ions carry about 30 % of the current through the electrolyte. Most of the remaining current is carried by the slower moving divalent nickel and sulfate ions, since the concentration of hydrogen ions is negligible. The boric acid, which exists largely as undissociated molecules, acts as a buffer to maintain the pH of the solution below 6. The presence of boric acid thus prevents the precipitation of nickel(II) hydroxide at the surface of the cathode by the reaction between nickel ions and hydroxide produced in the minor cathodic reaction involving the electrolytic decomposition of water.

6.1.4. *Electrorefining Operations*

Although it is not currently operated in North America or Western Europe, the refining of metallic nickel anodes is still practiced in the former Soviet Union. The Severonikel complex at Monchegorsk in the Kola peninsula has the capacity to produce 142 000 t/a of electrolytic nickel [44]. The Monchegorsk smelter treats a blend of high-grade nickel – copper ores, concentrates, mattes, and scrap from the nickel mining operations at Norilsk and Pechenga. Separate nickel and copper sulfide concentrates are produced by the slow-cooling matte separation process. The nickel sulfide is dead roasted at 1170 °C with oxygen-enriched air (25 % O_2), and the oxide calcine is reduced with coke in a rotary kiln to form a metallized oxide, which is melted at 1550 °C in an electric arc furnace for anode casting. About 3 % of the metallized oxide powder from the reduction kiln is retained for use in electrolyte purification. The anodes typically weigh 350 kg and analyze (wt %): 86 – 88 Ni, 2 Co, 4.5 Fe, 4 Cu, and 0.2 S.

The anodes are refined in an electrolyte containing 75 – 78 g/L Ni, 130 – 150 g/L SO_4^{2-}, 14 g/L Cl^-, and 6 g/L H_3BO_3, at pH 2. Each electrolytic cell contains 43 anodes and 42 cathodes, and operates at a current density of 250 A/m^2. The cathodes are enclosed in a synthetic fiber bag supported on a polypropylene frame. Starting sheets are produced by plating nickel on to titanium blanks for 24 h. The sheets are stripped manually. The anode cycle is 30 d, while the cathode cycle is four or six days. Anode slimes are recovered by washing adhering material off the corroded anodes, and from the bottom of the electrolytic cells, at the end of each anode cycle, for subsequent processing to recover precious metal values.

Impure anolyte solution is treated to remove iron, copper, and cobalt, and to replenish the nickel content of the electrolyte, before the purified solution is returned to the cathode compartments. Iron is removed by controlled oxidation with chlorine and neutralization with nickel carbonate. Copper is precipitated by cementation on nickel powder from the reduction kiln, and cobalt is precipitated by oxidation with chlorine and hydrolysis with nickel carbonate under highly oxidizing conditions. The nickel content of the solution is replenished by pressure leaching nickel sulfide concentrate (Ni_3S_2) in sulfuric acid solution under 1 MPa air pressure in vertical titanium autoclaves.

The electrorefining of nickel sulfide anodes is carried out by Inco at its Thompson operation in Canada, by Sumitomo Metal Mining Company at Niihama in Japan, and at Jianchuan in China.

The Thompson smelter [76] produces sulfide anodes by casting molten converter matte (73 % Ni, 0.8 % Co, 2.5 – 3.0 % Cu, 0.5 % Fe, and 20 % S) directly into anodes weighing ca. 240 kg. The cast anodes are cooled slowly over about 36 h to improve their mechanical handling characteristics, but are nevertheless more brittle than metal anodes and require careful handling.

The sulfide anodes are electrolyzed in diaphragm cells in a sulfate – chloride electrolyte. Nickel, cobalt, and copper dissolve from the anode, while sulfur, selenium, and the noble metals form an insoluble sludge or slime, from which they can be recovered. Nickel is plated on to pure nickel starting sheets, made by manually stripping 24-h deposits from stainless steel blanks. The anode cycle is 15 d and the cathode cycle is 10 d. Plating is carried out at a current density of 240 A/m^2. Details of the tankhouse operating parameters are as follows [76]:

Capacity	45 000 t/a Ni
Cells	608
Cell dimensions	1.6 m×0.9 m×5.8 m
Cell construction	fiber reinforced plastic lined precast concrete
Anode weight	238 kg
Anode dimensions	1.1 m×0.7 m×63 mm

Anode spacing	210 mm
Anodes/cell	27
Anode cycle	15 d
Cathode dimensions	1.0 m×0.7 m×13 mm
Cathode weight	88.5 kg
Cathodes/cell	26
Cathode cycle	10 d
Electrolyte flow	0.64 m^3/h per cell
Electrolyte temperature	50 °C
Current density	240 A/m^2
Cell voltage	3 – 6 V

The anolyte purification circuits at Thompson remove copper and arsenic by precipitation with hydrogen sulfide. The nickel content of the electrolyte is then replenished by reacting the solution with ground matte anode scrap under oxidizing conditions. For every 100 kg of nickel plated out in the tankhouse only 87 kg dissolves from the anode. This discrepancy is caused by the dissolution of 4 kg of copper, 1 kg of cobalt, 0.5 kg each of iron and arsenic, and by the formation of 0.2 kg of hydrogen ions. In the final stage of purification cobalt and iron are oxidized and hydrolyzed by the addition of chlorine and nickel carbonate. The cobalt(III) hydroxide precipitate is worked up for cobalt recovery. The purified electrolyte typically contains 75 g/L Ni, 120 $g/L\ SO_4^{2-}$, 28 g/L Na, 50 g/L Cl^-, and 8 g/L boric acid.

Until 1984, the principal products of the Thompson refinery were full nickel cathodes and cut shapes, made by shearing cathodes grown on nickel starting sheets. Now about 40 % of the refinery's production is “S” and “R” Rounds for the plating industry, which are made by plating nickel directly on to stainless steel blanks, covered by a heat-set epoxy mask, with circular areas of steel exposed to plating. Metallurgical data for the Thompson refinery, including the cathode nickel analysis, are given in Table 11.

Table 11. Metallurgical data for the Inco Thompson refinery [76]

Element	Anode, %	Anolyte, g/L	Purified electrolyte, g/L	Electronickel, g/t
Ni	73		75	
Co	0.8	0.13	0.02	600
Cu	3.0	0.50	0.0007	25
As	0.2	0.03	0.0005	30
Fe	0.6	0.03		5
Pb	0.003			2
S	20			7

6.2. Electrowinning

Electrowinning differs from electrorefining in that it is used to recover nickel from a leach liquor and can therefore be carried out with an insoluble anode, since the only function of the anode is to transfer electrons from the electrolyte to the external circuit. The electrowinning of nickel is practiced commercially with both pure sulfate and pure chloride electrolytes. In the sulfate system the anodes are made of chemical lead or antimonial lead, which have a relatively long life in sulfate solution, although soluble in chloride solutions. In the highly corrosive chloride system, dimensionally stable anodes (DSA), made by coating a titanium substrate with a platinum group metal oxide, are used.

The principal anodic reaction in the sulfate system is the decomposition of water to produce gaseous oxygen:

$$2\,H_2O \rightarrow O_2 + 4\,H^+ + 4\,e^-$$

The main cathodic reaction, as in electrorefining, is the deposition of nickel ions to form nickel atoms on the cathode:

$$Ni^{2+} + 2\,e^- \rightarrow Ni$$

The overall cell reaction is:

$$2\,NiSO_4 + 2\,H_2O \rightarrow 2\,Ni + 2\,H_2SO_4 + O_2$$

The sulfuric acid generated at the anode is utilized by recirculating the anolyte to the leach circuits.

In the chloride system the principal anodic reaction is the oxidation of chloride ion to chlorine gas:

$$2\,Cl^- \rightarrow Cl_2 + 2\,e^-$$

The overall reaction is thus the decomposition of nickel(II) chloride to metallic nickel and chlorine gas:

$$NiCl_2 \rightarrow Ni + Cl_2$$

The chlorine liberated at the anode is recycled for use in the leach circuits. In practice some decomposition of water also occurs to yield small quantities of hydrogen at the cathode and oxygen at the anode.

6.2.1. *Electrowinning from Sulfate Electrolytes*

In a sulfate electrowinning system the cathodes are suspended in bags, even though the nickel sulfate solution is purified before it enters the tankhouse. The cathode must still be protected from the anolyte, which is strongly acidic due to anodic generation of hydrogen ions. A high concentration of hydrogen ions at the cathode would result in the formation of hydrogen gas which is formed in preference to nickel deposition, thus seriously reducing the current efficiency of the cell.

Details of the purification methods used to remove copper, iron, lead, and cobalt from nickel sulfate leach liquor prior to electrowinning are given in Chapter Hydrometallurgy of Nickel Concentrates and Mattes . Treatment of electrowinning anolyte or spent electrolyte varies depending on the type of leaching circuit used. In the Outokumpu atmospheric leach, in which very little sulfur is oxidized, almost all the anolyte can be recycled to the leaching circuits, where the acid is neutralized in leaching nickel from the matte, thus replenishing the nickel content of the solution. Only a small solution bleed is taken out of the circuit to control the concentration of sodium sulfate, which would otherwise build up to unacceptable levels.

In the Sherritt acid pressure leaching process, as practiced by Rustenburg Refiners, in which all the sulfur in the matte is oxidized to sulfate, a much larger bleed of solution is required to maintain a sulfur balance. Typically 25 – 35 % of the anolyte stream must be removed from the circuit and treated to recover sodium sulfate. This bleed stream is reacted with sodium hydroxide or sodium carbonate to neutralize the acid and precipitate the remaining nickel as nickel(II) hydroxide or as basic nickel carbonate:

$$H_2SO_4 + 2\,NaOH \rightarrow Na_2SO_4 + 2\,H_2O$$

$$NiSO_4 + 2\,NaOH \rightarrow Ni(OH)_2 + Na_2SO_4$$

The nickel-free barren solution is evaporated to crystallize sodium sulfate. The precipitated nickel hydroxide or basic nickel carbonate is redissolved in a second portion of the anolyte stream to neutralize the acid content and replenish the nickel content:

$$Ni(OH)_2 + H_2SO_4 \rightarrow NiSO_4 + 2\,H_2O$$

This solution is recycled directly as feed solution to the electrowinning circuit. The balance of the anolyte is recycled for use in the matte leach circuits, where the acid is neutralized and the nickel content replenished, and passes through the leach solution purification steps before returning to the tankhouse.

The Outokumpu nickel refinery at Harjavalta in Finland contains 126 electrowinning cells, each having 40 insoluble lead anodes and 39 cathodes [1], [48], [67]. The bagged cathodes are nickel starting sheets made by the deposition of nickel for 48 h onto a stainless steel mother blank. The deposits are stripped manually and automatically made up into starting sheets. The purified solution is fed to the cathode compartments at a rate sufficient to maintain a hydrostatic head of about 30 mm. The current density is 200 A/m^2, giving a cell voltage of about 3.6 V. The cathode cycle is seven days. The cells are hooded to collect and remove the oxygen and acid mist generated at the anode.

The feed solution at pH 3.2, containing 75 g/L Ni as well as sodium sulfate and boric acid, is heated to 60 °C and fed separately to each cathode compartment. The solution passes through the diaphragm cloth into the anolyte, which overflows from each end of the cell. The anolyte, which contains 50 g/L Ni and 40 g/L H_2SO_4, is recycled to the leaching circuits. The cathodes typically weigh ca. 75 kg and contain 99.95 % Ni.

6.2.2. *Electrowinning from Chloride Electrolytes*

In the Falconbridge chloride electrowinning system [73], the dimensionally stable anodes are enclosed in a polyester diaphragm bag, to contain the chlorine gas generated in the anode reaction, and channel it to a vacuum hood fitted to the top of the anode. Ducts, connecting the top of the hood with a manifold that runs alongside the tank, allow the withdrawal of both chlorine and anolyte by suction. Purified solution is fed in at one end of the cell, and the solution level is held constant by maintaining a small overflow at the other end, while the greater portion of the electrolyte is withdrawn as anolyte with the chlorine gas.

The Falconbridge refinery at Kristiansand, Norway, which has a capacity of 54 000 t/a Ni, contains 326 electrolytic cells, of which 24 are devoted to starting sheet production. Each cell contains 46 anodes and 45 cathodes with an anode spacing of 145 mm. Typical operating parameters are as follows:

Inlet flow	4.0 m^3/h per cell
Total current	24 000 A
Current density	220 A/m^2

Current efficiency	98 – 99 %
Electrolyte temperature	60 °C
Catholyte Ni	60 g/L
Anolyte Ni	54 g/L

The refinery produces both regular nickel cathodes and Falconbridge crowns. The regular cathodes are produced by plating onto nickel starting sheets and are sheared to a variety of sizes for the nickel plating industry. Crowns weighing 30 – 60 g are produced by plating nickel onto specially designed cathode blanks, from which they are stripped and polished for market. The refinery produces a limited amount of exceptionally pure superelectro nickel, with less than 100 g/t of impurities including oxygen, and less than 5 g/t Co, by using a specially purified electrolyte.

6.3. Carbonyl Refining [1], [79], [80]

The reaction of carbon monoxide at atmospheric pressure with active nickel metal at 40 – 80 °C to form the gaseous nickel tetracarbonyl was discovered by LANGER and MOND in 1889 [75]. The reaction is readily reversible, with nickel tetracarbonyl decomposing to metallic nickel and carbon monoxide at 150 – 300 °C.

Nickel tetracarbonyl is a volatile liquid that melts at –19.3 °C and boils at 42.5 °C.

Under the mild conditions employed for reaction at atmospheric pressure, the carbonyl-forming impurities in crude nickel metal do not volatilize. Iron forms a volatile carbonyl, iron pentacarbonyl, $Fe(CO)_5$, with a freezing point of –20.5 °C and a boiling point of 103 °C, but the rate of formation is slow. Cobalt forms $Co_2(CO)_8$, which melts at 51 °C and decomposes at 52 °C to form $Co_4(CO)_{12}$, but both are solids with low volatility. Copper, like most other elements, does not form carbonyls directly with carbon monoxide. Thus the extraction of nickel as a carbonyl from a crude metal feed is a highly selective process.

The formation of metal carbonyls by the interaction of carbon monoxide with reduced metals can be catalyzed. In fact if it were not for the large increase in reaction rate resulting from the addition of a controlled amount of catalyst, the tonnage extraction of nickel and iron as carbonyls from reduced metals would probably not be feasible. With the aid of catalysts or inhibitors it is possible to produce the carbonyls of nickel, cobalt, and iron either selectively or together.

Although catalysts such as ammonia, mercury, selenium, and tellurium have been used to increase the rate of nickel carbonyl formation, sulfide activation is normally used. Sulfur is a good, low cost catalyst which can be added in the form of hydrogen sulfide, carbonyl sulfide, or sulfur dioxide. It may be added during the reduction step or prior to volatilization. The carbonyl extraction process is notable not only for its selectivity in the volatilization of the metals as carbonyls but also for the relative ease with which the carbonyls can be separated and decomposed under mild conditions to produce high-purity metals. Nickel and iron carbonyls can be separated by simple fractional distillation as a result of the large difference in their boiling points.

The carbonyl process makes it possible to produce nickel of very high purity with an exceptionally low cobalt content, which makes it particularly useful for nuclear energy applications.

The thermal decomposition of nickel tetracarbonyl is carried out by two different methods. Very rapid heating of the gas phase produces a fine nickel powder. Alternatively if the carbonyl contacts a hot metal surface, nickel deposits on the surface. This effect is used to produce nickel granules by the successive deposition of layers of nickel onto a seed particle, until the required size is attained.

6.3.1. *Atmospheric Pressure Carbonyl Process [1], [75]*

The Inco nickel refinery at Clydach, Wales, began operation in 1902 using the Langer – Mond atmospheric pressure carbonyl process. Originally the plant treated nickel – copper matte, but it now processes a granular nickel oxide, produced by fluidized-bed roasting of nickel sulfide at Inco's Copper Cliff smelter, which typically analyzes 74 % Ni, 2.5 % Cu, 1.0 % Co, 0.3 % Fe, and 0.1 % S.

The refinery still uses the basic Langer – Mond process but the operation has been greatly increased in efficiency over the years. The first three steps in the process—reduction, sulfide activation, and volatilization—are now carried out in rotary kilns. The nickel oxide is first reduced to metal at 425 °C by countercurrent contact with preheated hydrogen gas. The metal is then sulfided in a smaller kiln to activate it, before being contacted countercurrently with carbon monoxide at 50 – 60 °C and atmospheric pressure in a third kiln. About 95 % of the nickel volatilizes under these conditions but iron and cobalt are not carbonylated. The residue from the volatilizers is returned to Canada and forms part of the feed to the converters at the Copper Cliff nickel refinery.

The off-gas from the volatilizer kiln, which contains about 16 vol % nickel carbonyl, is fed to a pellet decomposer (Fig. 13) where it is contacted with preheated nickel granules at 200 °C. The nickel carbonyl decomposes, releasing carbon monoxide and depositing a layer of metallic nickel on the granules, which steadily increase in size.

Figure 13. Cutaway view of a pellet decomposer

a) Bucket elevator; b) Preheater chamber; c) Reaction chamber

The decomposer is filled with about 30 t of pellets which flow downwards by gravity and are recirculated to the top of the vessel by an enclosed bucket elevator. As the pellets pass downwards they are heated to 200 °C before contacting the carbonyl-containing gas introduced at the bottom of the decomposer. The motion of the pellets prevents them from adhering together. Nickel powder is added periodically to nucleate new pellets, and market-size pellets (8 mm) are automatically segregated from the smaller material and discharged. The off-gas from the decomposer contains ca. 93 vol % carbon monoxide and 0.1 % nickel carbonyl, and is recycled to the volatilization kiln. Nickel pellets from the carbonyl process typically contain 99.97 % Ni and less than 5 g/t Co. In addition to nickel pellets, carbonyl nickel powder is also produced at Clydach in electrically heated powder decomposers and accounts for ca. 20 % of the refinery nickel output.

6.3.2. *High-Pressure Carbonyl Process (BASF)*

Extraction of nickel with carbon monoxide is also used in processes that operate at high pressure and produce liquid nickel carbonyl. The volume change that occurs in the carbonyl reaction:

$$Ni + 4\,CO \rightarrow Ni(CO)_4$$

with four molecules of carbon monoxide forming one molecule of nickel carbonyl, means that an increase in pressure accelerates the formation of the carbonyl. The increased pressure stabilizes the carbonyl and thus permits the process to be carried out at high temperature, which further increases the rate of reaction. As a result, activation of the nickel feed material is no longer necessary, and a wider range of feeds can be processed.

BASF in Germany operated a high-pressure carbonyl nickel refining process from 1932 until 1964. The feed materials were nickel – copper matte or nickel scrap and residues. The feeds were melted and the composition was adjusted to provide just enough sulfur to combine with copper as Cu_2S and with part of the iron. The molten feed was granulated and reacted with carbon monoxide at 230 °C and 20 MPa. Over 95 % of the nickel was extracted as nickel carbonyl in a three-day batch treatment. Some iron was also carbonylated. Pure nickel powder was obtained by fractionation of the liquid carbonyls, and rapid heating of nickel carbonyl vapor to 280 –300 °C.

6.3.3. *Inco Pressure Carbonyl Process [80], [81]*

The newest application of carbonyl refining to the treatment of a nickel- containing feed material is Inco's nickel refining complex in Copper Cliff, Ontario, which was commissioned in 1973. This plant has a nominal capacity of 57 000 t/a of refined nickel.

The refinery consists of two operating plants: the converter plant and the pressure carbonyl plant. The converter plant produces granulated metallic nickel with a controlled sulfur content, using two top-blown rotary converters (TBRC's). The pressure carbonyl plant produces 45 000 t/a of nickel pellets, 9000 t/a of nickel powder, and 2200 t/a of ferronickel byproduct from the granulated, sulfided nickel feed.

The principal feed materials supplied to the refinery by the Copper Cliff smelter are the metallics fraction from the matte separation process (Section Inco Matte Separation Process) and the less pure portions of the nickel oxide made by roasting the nickel sulfide concentrate (Section Fluidized-Bed Roasting of Nickel Sulfide) as well as various other nickel-bearing residues and intermediates. The novel feature of this process is the preparation of a nickel feed material which could be carbonylated at moderate pressure without the need for a separate activation step.

Figure 14 shows the process flow sheet for the preparation of the feed material in the converter plant. The feed materials are blended and smelted in two 50 t capacity top-blown rotary converters (Fig. 15). Smelting is a batch operation carried out in three phases: charging/melting, blowing (sulfur removal), and reduction. In the charging/melting phase, blended feed materials are charged as the furnace rotates and is fired with a natural gas – oxygen flame from a watercooled lance. Coke is blended with the feed to reduce its oxide content, and the oxygen content of the flame is adjusted depending on the amount of sulfur to be removed. Charging is finished when the oxides have been reduced and the temperature of the melt is about 1500 °C. During the charging and blowing phase the furnace is rotated to minimize dust emissions.

Figure 15. Cutaway view of a top-blown rotary converter

a) Water-cooled charging chute; b) Flue; c) Track ring; d) Water-cooled oxygen/natural gas lance; e) Hood; f) Rotate drive motor; g) Thrust roller

In the blowing phase, a precalculated amount of high-pressure oxygen is blown at supersonic velocities into the converter charge to oxidize sufficient sulfur to produce a matte with a Cu/S ratio of about 4 : 1 (Cu_2S). In the reduction phase, oxides formed during blowing and oxygen dissolved in the bath are reduced with petroleum coke. Some sulfur removal also occurs when oxygen dissolved in the matte reacts with remaining sulfides. The converter is rotated at 15 rpm during reduction. Off-gases are drawn out through a movable hood and cleaned in electrostatic precipitators before being vented to a stack. The recovered dusts are recycled to a subsequent converter charge.

Molten matte at 1600 °C is granulated with high-pressure water jets at a rate of 1 t/min. The granulated matte is dried and transferred to the pressure carbonyl plant. The matte typically analyzes 75 – 80 % Ni, 12 – 17 % Cu, 2 % Co, 2 % Fe, and 3 – 4 % S, with a granule size of less than 9 mm.

Figure 16 shows the process flow sheet for the pressure carbonyl refining operation. Matte granules are carbonylated in 150-t batches at temperatures up to 180 °C and pressures of 7 MPa in three horizontal cylindrical rotating reactors (Fig. 17). Carbon monoxide is continually circulated through the reactor. Nickel carbonyl formation is very exothermic and the heat of reaction is removed by means of water- cooled heat exchanger tubes inside the reactors, which also serve as lifters to improve gas – solids contact as the vessel rotates. Micro-metallic filters at each end of the reactor prevent loss of solids entrained in the gas stream. The direction of gas flow is reversed periodically to prevent filter blinding.

Nickel and iron carbonyls are carried out of the reactor with the carbon monoxide stream, are liquified by cooling, and stored as liquids at atmospheric pressure. The carbonylation reaction normally extracts about 97.5 % of the nickel and 30 % of the iron, leaving a residue typically containing 57 % Cu, 8.5 % Ni, 9 % Co, 6 % Fe, and 15 % S, as well as the precious metals. The residue is treated hydrometallurgically to recover copper, cobalt, nickel, and the precious metals [82].

The crude, liquid nickel – iron carbonyls typically contain 98.9 % Ni and 1.1 % Fe. This liquid is fractionated in two columns, each with twenty trays, to separate nickel carbonyl (*bp* 43 °C) from iron carbonyl (*bp* 103 °C). Distillation is carried out at below boiling temperatures with carbon monoxide as a carrier gas. Nickel carbonyl, which is obtained as a mixture of vapor and liquid from the overhead partial condensers, is used to make extremely pure nickel powder and pellets. The bottoms from the reboilers, which contain 85 % iron carbonyl and 15 % nickel carbonyl liquids, are decomposed to form ferronickel pellets.

The nickel carbonyl vapor from the distillation column passes directly to pellet decomposers (see Fig. 13) where it is contacted with preheated nickel pellets at 240 – 270 °C. The operation of the decomposers is essentially as described in Section High-Pressure Carbonyl Process (BASF) for the Inco refinery at Clydach. The condensed portion of the nickel carbonyl distillation overhead stream is revaporized with carbon monoxide carrier gas to avoid premature decomposition and passed to electrically heated powder decomposers (Fig. 18). Decomposition by thermal shock at 300 °C produces pure nickel powder, which can be varied in shape, size, morphology, and density by adjusting the operating conditions.

Figure 18. Cutaway view of a powder decomposer

a) Baghouse; b) Decomposer; c) Electric heaters; d) Connecting box; e) Discharge container

The iron carbonyl-containing bottoms product from distillation is treated by revaporizing the liquid at a sub-boiling temperature with carbon monoxide as carrier gas, and feeding it to a pellet decomposer to produce ferronickel pellets.

The pure nickel pellets, with a typical diameter of 10 mm, analyze over 99.97 % Ni with 60 g/t C, 40 g/t O_2, and less than 0.2 g/t Co. The nickel powder, with a particle size in the range 3 – 7 µm, has significantly higher carbon and oxygen contents (650 g/t C and 570 g/t O_2).

6.4. Hydrogen Reduction to Nickel Powder [1], [65]

Nickel is recovered as a pure metal powder from nickel sulfate leach solutions by chemical reduction with hydrogen under pressure in several hydrometallurgical nickel refineries. Precipitation of the metal is carried out with an ammoniacal nickel sulfate solution having a molar ratio of ammonia to nickel of 2 : 1, so that the acid generated in the reduction reaction is neutralized by reaction with ammonia to form ammonium sulfate:

$$[Ni(NH_3)_2(H_2O)_4]SO_4 + H_2 \rightarrow Ni + (NH_4)_2SO_4 + 4\,H_2O$$

The reduction process is operated at 200 °C at a hydrogen pressure of 3 MPa in horizontal single-compartment autoclaves, each equipped with four agitators. The solution is processed batchwise, with the powder particles growing as successive layers of nickel are reduced, onto seed particles, from up to sixty batches of nickel-bearing feed solution. After each reduction or densification, which takes up to thirty minutes, the powder is allowed to settle, and the depleted solution is decanted off and replaced by fresh feed solution.

The nickel precipitation reaction can occur on any metal surface, and in the absence of suitable seed particles most of the metal deposition occurs on the vessel walls as a solid plate. When suitable seed particles such as fine nickel powder are available, most of the nickel deposits on these particles, but even so, a minor but significant amount of nickel still plates on the walls, and must be releached periodically. Normally this plating leach is carried out after each cycle of 50 – 60 densifications, and the leach liquor produced is used to prepare the seed particles for the subsequent densification cycle.

Seed particles are produced by adding an aqueous solution of iron(II) sulfate to the plating leach liquor to form a finely divided precipitate of ferrous hydroxide, and applying a hydrogen overpressure of 2.5 MPa at 115 °C. Under these conditions the nickel deposits onto the nuclei of ferrous hydroxide to form very fine particles of nickel metal, which provide the seed particles for densification. Once the nickel seed particles are formed, subsequent nickel deposition occurs autocatalytically on the surface of the particles, in preference to the vessel walls.

The reduction reaction is selective for nickel from a solution containing 50 g/L Ni and 1 g/L Co until the nickel content drops to about 1 g/L. Reduction is normally stopped at this point, leaving a solution containing about 1 g/L Ni and 1 g/L Co. This solution is reacted with hydrogen sulfide to precipitate a mixed nickel – cobalt sulfide, which is treated hydrometallurgically to recover refined cobalt (Section Ammonia Pressure Leaching), while the barren solution is evaporated to crystallize ammonium sulfate for sale as fertilizer.

At the end of a densification cycle when the powder has reached the desired particle size and density, the whole contents of the autoclave are discharged under pressure to a cone-bottomed flash tank. The solution is drawn off and the nickel powder is withdrawn from the bottom of the tank as a slurry containing 95 % solids. The powder is washed with water and collected on a vacuum filter. The filter cake is dried in a rotary dryer fired with natural gas. The powder is either marketed as such or is converted to briquettes by mixing with an organic binder and pressing in briquetting rolls. The “green” briquettes are sintered and desulfurized at 950 °C in a reducing atmosphere.

The powder typically analyzes 99.8 % Ni, 0.08 % Co, < 0.001 % Cu, 0.002 % Fe, 0.001 % C, 0.025 % S, and 0.02 % O_2.

This process for recovering nickel powder from solution can be used in combination with the ammonia pressure leaching of nickel concentrates and mattes (as at Sherritt Gordon and Western Mining Corporation), with the acid pressure leaching of nickel – copper mattes (as at Impala Platinum and in the former Amax operation at Port Nickel), and with the Caron process for treating nickel laterites (as at Nonoc in the Philippines).

7. Beneficiation of Oxide Ores [1]

As described in Chapter Occurrence, nickel oxide ores occur in two types: a limonitic type which occurs in the upper zone of a lateritic deposit, in which ferric oxide materials are predominant, and a silicate, or “garnierite” type, occurring at greater depth in the deposit, which has a lower iron content, but is usually richer in nickel than the limonite, and contains high levels of magnesia and silica. In nickeliferous limonite $(Fe,Ni)O(OH) \cdot nH_2O$ the nickel oxide is mainly present in solid solution with the iron oxides. In nickeliferous silicate, nickel, iron, and cobalt oxides occur in varying proportions, generally replacing part of the magnesium oxide in the serpentinite $[Mg_6Si_4O_{10}(OH)_8]$.

Most deposits contain both types of ore. Usually it is possible to separate the ore by selective mining and screening into an iron-containing limonite fraction and a magnesium silicate fraction enriched in nickel. The metallurgy of nickel oxide ores differs from that of sulfides in that oxide ores are not amenable to most of the standard mineral beneficiation methods due to the chemical dissemination of the nickel in the oxide minerals. Screening may be used to reject the oversize, less weathered fragments that contain less nickel, but this provides only a minor degree of upgrading.

In most cases the ore is treated directly by a pyrometallurgical or hydrometallurgical process. However, two processes have been developed in which the nickel is first converted by high-temperature treatment to a metallic phase, which can then be

separated from the bulk of the ore by standard mineral beneficiation techniques. These processes are the Nippon Yakin Oheyama process (which was based on the Krupp – Renn process developed in Germany in the 1930s to produce iron from otherwise uneconomic low-grade iron ores) and the MINPRO – PAMCO segregation process.

7.1. The Nippon Yakin Oheyama Process [83]

Nippon Yakin Kogyo produces 12 000 t/a nickel as low-nickel ferronickel from silicate ores (2.3 – 2.6 % Ni, 12 – 15 % Fe), imported from New Caledonia, the Philippines, and Indonesia, at its Oheyama works in Japan. The ore is ground and mixed with anthracite, coal, and flux, and briquetted. The briquettes are fed continuously through a rotary kiln, countercurrent to a flow of hot gas produced by the combustion of coal. As the temperature rises from 700 °C to 1300 °C, the charge is successively dried, dehydrated, and reduced. As the charge begins to melt, smelting occurs in the semifused state to form coalesced particles of spongy ferronickel (known as luppen, from the Krupp – Renn process) interspersed in a viscous slag phase. The kiln discharge is quenched in water and the luppen are separated from the slag by grinding, screening, jigging, and magnetic separation. Nickel recovery from ore is typically 95 %.

A major advantage of this process is that the ferronickel product is recovered in the form of 2 – 3 mm particles containing 22 % Ni + Co, 0.45 % S, 0.03 % C, and 0.02 % P which can be used directly in the AOD steel making process, without further upgrading or refining. Although the process is energy intensive, the major energy sources used are cheap anthracite and coal, and no high cost electrical energy or oil is used for heating. Consequently, energy costs are relatively low.

7.2. Segregation Processes [84], [85]

The segregation process was developed to recover copper from refractory minerals such as silicates, and has been applied with limited success on a commercial scale in Africa. Research has shown that the technique can be applied to the production of ferronickel from several types of nickel laterite ore, but the process has not yet been successfully applied on a commercial scale.

In the segregation process the ore is treated with a halide such as calcium chloride and a reductant such as coke at temperatures well below the melting range (950 – 1100 °C). Under these conditions the halide reacts with silicates and water vapor to form hydrogen chloride.

$$CaCl_2 + SiO_2 + H_2O \rightarrow CaSiO_3 + 2\,HCl$$

Iron(III) oxide is reduced to iron(II) oxide by hydrogen and carbon monoxide, which are formed in the reaction between coke and water.

$$C + H_2O \rightarrow CO + H_2$$

$$Fe_2O_3 + CO \rightarrow 2\,FeO + CO_2$$

$$Fe_2O_3 + H_2 \rightarrow 2\,FeO + H_2O$$

The gaseous hydrogen chloride chloridizes both nickel oxide and iron(II) oxide to form the volatile metal chlorides.

$$FeO + 2\,HCl \rightarrow FeCl_2 + H_2O$$

$$NiO + 2\,HCl \rightarrow NiCl_2 + H_2O$$

The metal chlorides are reduced to metal by reaction with hydrogen at the surface of the coke particles,

$$FeCl_2 + NiCl_2 + 2\,H_2 \rightarrow FeNi + 4\,HCl$$

releasing hydrogen chloride to react with further nickel and iron oxides. The ferronickel collects on the particles of coke and can be separated from the silicate phases by grinding and magnetic separation.

A major obstacle to the commercial development of this process has been the lack of a suitable reactor. The most promising approach, which was successfully tested at a rate of 1 t of ore per hour in 1981 – 1983, is the MINPRO – PAMCO segregation process. The reactor employed was a 850 kW former autogenous grinding mill, which was relined with two courses of refractory brick to permit operation at 950 °C.

In the pilot testwork, a nickel ore containing 2.3 % Ni and 13.2 % Fe was preheated in a rotary kiln to 950 °C, and treated in the segregation reactor with 40 kg calcium chloride and 20 kg coke per tonne of ore. The reactor discharge was cooled and ground prior to magnetic separation to yield a ferronickel product grading 59 % Ni and 29 % Fe, and a tailing with 0.45 % Ni. Further upgrading to 68 % Ni was shown to be possible with additional grinding and magnetic separation steps. Energy savings of 25 – 30 % over the conventional smelting process have been projected by the developers of the process.

[Top of Page]

8. Pyrometallurgy of Oxide Ores [1], [7], [8], [29]

Nickel laterite ores have historically been treated almost exclusively by smelting processes, and except for Cuba, where nickel ore treatment is all essentially hydrometallurgical, the industry is still predominantly pyrometallurgical. The development of nickel oxide ore smelting has drawn heavily on iron and steel metallurgy for ferronickel production and on copper metallurgy for nickel matte production.

The separation of nickel from the refractory oxides is relatively simple because there are large differences in the free energies of formation of nickel oxide and the gangue components such as silica and magnesia. Adjustment of the reduction conditions permits the complete reduction of nickel oxide while limiting the degree of reduction of iron oxide, but a total separation of nickel from iron by selective reduction is not possible. Two major process routes have been developed to overcome this problem.

In ferronickel production, the nickel oxide and part of the iron oxide are reduced to metal in an electric furnace. The fraction of iron reduced to metal is a function of the reduction potential of the system, so that ores with a low Ni/Fe ratio can be smelted to yield an acceptable ferronickel grade.

In nickel matte production, the ore is smelted with a reductant, a flux, and a source of sulfur, which may be gypsum, a sulfide mineral, or elemental sulfur. Most of the nickel and a large portion of the iron are reduced and sulfidized to form a low-sulfur matte phase. Iron removal can then be accomplished by fluxing and selective oxidation of the iron in a converter to produce a nickel matte containing over 75 % Ni, 20 – 22 % S, and less than 1 % Fe.

The smelting of nickel silicate ores in blast furnaces was developed by Societé Le Nickel (SLN) in New Caledonia in the 1870s [86]. Initially, attempts were made to produce ferronickel, but after encountering difficulties in eliminating sulfur from the product, the operation switched to the production of nickel – iron sulfide matte. The furnace matte was blown to give a low-iron converter matte, which was shipped to Europe or North America where it was dead roasted to remove sulfur and reduced in briquette form with charcoal to metal rondelles. The SLN introduced electric furnace smelting of nickel silicate ores to ferronickel in 1958, using a furnace design developed by Elkem – Spigerverket of Norway, and most present-day ferronickel smelters use processes based on this technology [87].

Several of the world's major nickel laterite smelters are listed in Table 12 together with details of their ore and product nickel grades and production capacities.

Table 12. Nickel laterite smelters

Smelter	Ore grade, % Ni	Product		1988 production, t/a Ni
		Type	Grade, % Ni	
SLN, New Caledonia	2.70	Fe – Ni	25	37 000
		matte	78	10 000
P.T. Inco Indonesia	1.97	matte	79	28 000

* 1985 production data.

8.1. Ore Pretreatment

Nickel laterite ores have high moisture contents (typically up to 45 %) as well as chemically bound water in the hydroxide form. All ore treatment plants use dryers, usually direct-fired rotary units operating at about 250 °C, which reduce the moisture content only to 15 – 20 % to minimize dusting during drying and subsequent smelting. Calcining to dehydrate the ore and prereduction prior to electric furnace smelting are generally carried out in countercurrently fired rotary kilns. Chemically bound water is released above ca. 400 °C, and reduction of the oxides to metal starts at 500 – 600 °C. The maximum temperature reached in the kiln is generally limited to 800 – 900 °C because of the tendency of the ore to agglomerate and form accretions on the furnace walls. Dehydration and prereduction of the ore in the kiln prior to smelting, optimizes the utilization of energy available from the reductants and fuel, thus reducing energy consumption in the smelting operation.

8.2. Smelting to Ferronickel

The rotary kiln – electric furnace smelting process is now used almost universally for the production of ferronickel from oxide ores. Nippon Mining shut down the last blast furnace producing ferronickel, at Saganoseki in Japan, in 1985 [88]. Variations on the electric furnace ferronickel process, which were developed in the 1950s by Ugine (France) and by Falconbridge in the 1960s, made it possible to achieve a more selective reduction of nickel, and thereby produce higher nickel grade products from lower grade ores.

The first commercial scale electric furnaces to produce ferronickel were the 10.5 MVA units installed by SLN at its Doniambo smelter in New Caledonia in 1958. The largest units (as of 1989) in operation are a 51 MVA unit at Cerro Matoso in Colombia and a 60 MVA furnace at Pacific Metals at Hachinohe in Japan.

8.2.1. *The Rotary Kiln – Electric Furnace Process [87]*

In the earliest plants, the function of the rotary kiln was limited to drying and dehydrating the ore, and furnace operating temperatures did not exceed 700 °C. The hot calcine was then blended with reductant, usually coal, and transferred to the electric furnace where reduction of the metals occurred.

In the electric furnace the calcined ore was smelted with the reductant to form immiscible layers of slag and ferronickel. The New Caledonian ores, with their high magnesia and silica contents (2.5 % Ni, 10 – 15 % Fe), require no additional flux for slag formation. Virtually all the nickel and 60 – 70 % of the iron in the ore are reduced to metal to yield a ferronickel grading about 20 % Ni; the slag contains only 0.1 % Ni. The energy consumption in the electric furnace for this mode of operation is 2.0 – 2.2 GJ per tonne of dry ore (550 – 600 kWh/t).

As the process was developed and applied to a wider range of nickel laterite ores, several improvements in design and operating technique were made. The operating temperature of the rotary kiln was increased to 900 – 1000 °C, and reductant was added to the kiln feed to ensure a more complete dehydration of the ore and to allow a partial reduction of the metals to occur in the kiln. As a result energy consumption in the electric furnace was reduced to 1.8 – 2.0 GJ/t (500 – 550 kWh/t).

The degree of reduction achieved in the kiln depends on the composition of the ore and on the reactivity of the reductant. Iron and nickel silicate minerals are generally less reactive than nickel oxide minerals. Usually lignites and charcoal are the most reactive reductants, and high-volatile coals are more reactive than low-volatile coals, anthracite, or coke. Typically, under optimum conditions, up to 40 % of the nickel is reduced to metal in the kiln, while the iron oxides are reduced to iron(II) oxide (FeO).

In the electric furnace the charge must be heated to 1400 – 1650 °C to permit the separation of distinct slag and metal phases. The energy input to the charge is provided by radiation from the electric arcs around the tips of the electrodes and by the heat generated in the slag by resistance heating due to the flow of current through the slag layer between the electrodes. Since the electrical resistivity of the metal layer is much lower than that of the slag, very little heat is generated in the metal layer, which must therefore receive heat by conduction and convection transfer from the overlying slag layer. For satisfactory heat transfer, the temperature differential between slag and metal layers should be at least 100 °C.

The mode of operation of the electric furnace is largely determined by the melting temperature of the slag. Except for the limonitic ores, where the alumina and lime contents have a significant effect, the slag melting temperatures for a particular ore can be estimated from the FeO – MgO – SiO_2 equilibrium phase diagram (Fig. 19) [89]. For SiO_2/MgO weight ratios of less than 2 : 1, the slag melting temperatures are essentially independent of the FeO content. At high SiO_2/MgO weight ratios the slags are close to saturation with SiO_2, and the slag melting temperatures are then a function of the FeO content (Fig. 20) [29]. High iron contents, which normally occur with low-magnesia ores, result in the formation of highly corrosive low-melting (1350 – 1450 °C) slags. Since the use of magnesia or silica fluxes is usually uneconomic, the problem of low-melting slags must be overcome in the design and operating mode of the furnace [90].

Figure 19. The FeO – MgO – SiO_2 phase diagram

Figure 20. Slag melting point as a function of FeO content

Operation of the electric furnace is simplest when the slag melting temperature is higher than the metal melting temperature (1300 – 1400 °C). For such a system the furnace is operated with a covered bath (Fig. 21 A). The hot ore charge is allowed to build up on top of the molten slag, and the electrodes are not immersed in the slag layer. Under these conditions much of the reduction reaction occurs in the hot charge layer before it melts.

Figure 21. Electric furnace operation

A) Covered bath; B) Open bath

a) Metal pool; b) Slag bath; c) Electrodes; d) Solid charge; e) Slag tap hole; f) Metal tap hole

The high-iron limonite ores, which produce slags with melting points well below the melting point of the metal phase, can be smelted if the distance between the electrode tips and the slag-metal interface is reduced significantly. The electrodes must therefore penetrate deeply into the molten slag layer (Fig. 21 B). A vertical temperature gradient is then set up in the slag layer, with the highest temperature around the electrode tips. Under these conditions it is possible to operate the furnace with a metal tapping temperature higher than the slag tapping temperature. However the deep immersion of the electrodes in the slag results in a significant reaction between the carbon of the electrodes and metal oxides in the slag, with the evolution of carbon monoxide around the electrodes. The evolution of gases makes covered bath operation of the furnace impractical, and necessitates open bath operation (Fig. 21 B) with the slag surface exposed around the electrodes [87].

The ferronickel grade produced in the electric furnace smelting operation can be closely controlled by the amount of solid reductant added to the process. For a given addition of reductant, nickel recovery is highest, followed by cobalt, and iron recovery to the metal phase is lowest. Generally as much as 60 – 70 % of the iron is reduced from silicate ores, while only 10 – 15 % of the iron is reduced from high iron limonitic ores.

Normal operating practice is to produce up to 25 % Ni ferronickel from silicate ores and 15 – 20 % Ni ferronickel from limonitic ores. Nickel losses to the electric furnace slag under these conditions are quite low (0.1 % Ni in the slag). Nickel losses to slag increase with nickel grade, although grades with 35 – 45 % Ni can normally be produced from most ores without excessive losses (0.15 – 0.20 % Ni in the slag). Above 45 % Ni in ferronickel, slag losses increase rapidly. Where higher grades are required, the ferronickel electric furnace product can be upgraded by removing iron by oxidation and slagging in an oxygen-blown converter, and the high Ni content slag is recycled to the electric furnace. Ferronickel grades as high as 90 % nickel can be achieved with two stages of converter upgrading.

Current industrial practice is illustrated by the following descriptions of specific operations. In the Doniambo smelter of SLN in New Caledonia, which was built in 1958, the wet ores are carefully blended and screened to produce a smelter feed with an average composition of 2.5 – 3.0 % Ni and Co, 20 – 28 % MgO, 15 – 20 % Fe_2O_3, and 30 – 40 % SiO_2. The ore is blended with anthracite as a reductant and heated in a rotary kiln to 950 °C. Only a minor degree of reduction occurs in the kiln. The hot calcine is transferred to an electric furnace (one of eight 10.5 MVA or three 33 MVA units). Smelting is carried out with a charge covered bath, although the electrodes dip about 30 mm into the slag layer. Energy consumption is 90 MJ/kg Ni (2.35 GJ/t ore or 650 kWh/t ore) and electrode consumption is 1.5 kg/kg Ni (39 kg/t ore). Nickel and iron recoveries from ore to ferronickel product are 95 and 50 %, respectively. The slag tapping temperature is 1550 – 1600 °C, while the metal is tapped at 1450 °C. The slag, which typically contains 0.1 – 0.2 % Ni, is granulated and discarded [91], [92].

The crude ferronickel contains 24 % Ni, 69 % Fe, 2 % C, 3 % Si, 1.5 % Cu, and 0.25 % S. It is either cast into ingots for market, converted to nickel matte (Section Smelting to Nickel Matte), or desulfurized and refined to higher quality ferronickel. Ferronickel is marketed by SLN as 25 kg ingots and as granules.

Much the same process is used by the three Japanese ferronickel smelters, Pacific Metals at Hachinohe [93], Sumitomo at Hyuga [94], and Nippon Mining at Saganoseki, by Morro do Niquel in Brazil [95], by PT Aneka Tambang in Indonesia, and by Cerro Matoso in Colombia [96], [97]. All these operations process ores with relatively low Fe/Ni ratios of 6 : 1 or less. Representative ore and slag compositions are given in Table 13.

Table 13. Silicate ore and slag compositions [29]

Smelter	Ore composition, %				Slag composition, %		
	Ni	Fe	MgO	SiO_2	FeO	SiO_2	MgO
SLN	2.7	14 – 15	20 – 28	35 – 40	12	45	30
Hyuga	2.4	9 – 14	22 – 29	35 – 43	8	52	36
Morro do Niquel	1.25	6.5	30	43	7	50	30
Aneka Tambang	2.25	13	24	45	5	56	29
Cerro Matoso	2.9	14	15	46	22	59	20

The Cerro Matoso plant (built 1982) treats an ore with the exceptionally high SiO_2/MgO ratio of 3 : 1. The resulting acid slags have proved to be highly corrosive to furnace refractories. The dried ore (12 % moisture) is ground, blended with coal, and pelletized prior to entering the rotary kiln (Fig. 22). The kiln is operated at 900 – 950 °C with an oxidizing atmosphere and a reducing bed to achieve prereduction of 20 % of the nickel to metal, and up to 95 % of the iron oxide to the divalent state

(FeO). Smelting is carried out in a single 51 MVA electric furnace. The ferronickel, grading over 40 % Ni, is tapped at 1420 – 1440 °C, while the slag, containing 0.2 % Ni, is tapped at 1600 – 1630 °C. The ferronickel is refined and upgraded to 43 % Ni prior to being cast into 22 kg ingots, or granulated [96].

Figure 22. Flow sheet of the Cerro Matoso ferronickel smelter

a) Drying kiln; b) Screen; c) Batch bins; d) Reduction kiln; e) Electric furnace; f) ASEA/SKF Fe – Ni refining

The operation of LARCO at Larymna in Greece is an example of ferronickel production from a very low grade limonitic ore (1.2 – 1.3 % Ni, 31 – 35 % Fe). In this case a high degree of prereduction in the rotary kiln is essential. The ground ore is blended with lignite, coal, and heavy fuel oil, and heated to 920 °C in one of two countercurrently fired rotary kilns. The kiln discharge still contains about 3 % carbon, but is reported to contain no metallic nickel, while most of the iron oxides are reduced to FeO. The calcine is smelted in one of four electric furnaces (13 – 16 MVA) to produce a metal phase containing 15 % Ni, 0.02 % C, and 0.25 % S. The metal is tapped at 1520 °C and upgraded to 28 % Ni in an oxygen-blown converter. This treatment also reduces the sulfur content to 0.06 %. Energy consumption for the electric furnace is 125 MJ/kg Ni (1.6 MJ/t ore or 440 kWh/t ore) and electrode consumption is 0.4 kg/kg Ni (5 kg/t ore) [98].

8.2.2. *The Ugine Ferronickel Process*

In the rotary kiln – electric furnace process described in Section The Rotary Kiln – Electric Furnace Process excess carbon is normally added to the furnace charge to ensure quantitative reduction of nickel oxide. As a result more iron oxide is reduced to metal than is desirable, decreasing the ferronickel grade and leaving a high residual carbon level, typically 1 – 3 %, in the product. The excess iron and carbon are subsequently removed by oxidation with air or oxygen. Consequently the process is not particularly economical in terms of energy consumption.

A more selective method of nickel oxide reduction was developed by the French company Ugine in the early 1950s and applied commercially by Hanna Mining in their plant in Riddle, Oregon, in 1954. In this process the ore is dried and calcined in a rotary kiln and melted in an electric furnace without addition of reductant to produce a melt of iron and nickel oxides. No slag – metal separation occurs in the electric furnace. The molten ore is transferred to a ladle furnace where it is reduced by reaction with ferrosilicon at 1650 °C. The two phases are mixed by repeated pouring of the mixture from one ladle furnace to another. The nickel oxide and some of the iron oxide are reduced to metal. The balance of the iron is removed as slag.

$$2\,Fe_2O_3 + FeSi \rightarrow 4\,FeO + SiO_2 + Fe$$

$$2\,NiO + FeSi \rightarrow 2\,Ni + SiO_2 + Fe$$

$$2\,FeO + FeSi \rightarrow 3\,Fe + SiO_2$$

The reduced ferronickel contains 30 – 50 % Ni and very low levels of carbon and sulfur. The major impurity is phosphorus, which is removed by oxidation with iron ore and slagging with lime.

8.2.3. *The Falcondo Ferronickel Process [99]*

The Falconbridge ferronickel operation in the Dominican Republic treats a low-grade ore (1.5 % Ni, 17 % Fe, 24 % MgO, and 35 % SiO_2) by means of a specially developed process designed to provide a more selective reduction of nickel relative to iron than is possible in the rotary kiln – electric furnace process. Reduction of briquetted ore is carried out in shaft furnaces fired with a reducing gas, generated by cracking low-sulfur naphtha. No solid or liquid reductants are added to the furnace feed. A high degree of reduction of the ore is achieved in the shaft furnace, and the subsequent electric furnace step is required to do little more than melt the reduced calcine to allow separation of the metal and slag phases. The ferronickel produced is high grade (38 % Ni) and contains low impurity levels (< 0.04 % C and Si).

The Falcondo plant, which has a capacity of 35 000 t/a Ni, was commissioned in 1971. The ore is carefully blended to maintain a constant chemical composition, particle size, and moisture content, so that it can be briquetted without a binder. The briquettes are calcined and reduced in twelve open-top shaft furnaces. Each furnace is equipped with its own gasification reactor in which low-sulfur naphtha is cracked by combustion with a deficiency of air to produce reducing gas ($CO + H_2$). The hot reducing gas at 1250 °C is first cooled to 1150 °C before being supplied to the shaft furnace through the primary tuyeres. The gas flows upwards, countercurrent to the ore briquettes which are fed to the open top of the furnace. The gas reduces the nickel oxides to metal and the iron oxides to FeO. A portion of the partly reacted reducing gas is taken off from the top of the furnace, where it is mixed with a controlled amount of air and fed back into the furnace through secondary tuyeres located 1.8 m above the primary tuyeres. This stream provides the combustion fuel to dry and calcine the ore feed in the upper section of the shaft.

The hot reduced briquettes are discharged from the bottom of the shaft furnace at 800 °C and are transferred to one of three 55 MVA electric furnaces. The furnace operation consumes only 1.6 GJ/t (440 kWh/t) of charge. The crude ferronickel, which is tapped at 1475 – 1500 °C, contains 32 – 40 % Ni. The slag, containing about 0.15 % Ni, is tapped at 1500 – 1600 °C. The crude ferronickel, which typically contains only 0.15 % S, 0.03 % P, 0.04 % Si, and 0.02 % C, is refined to remove sulfur and phosphorus.

8.2.4. *Refining of Ferronickel*

The refining of ferronickel resembles that of steel in that the principal impurities are sulfur, carbon, silicon, phosphorus, and oxygen. Typical impurity levels in crude and refined ferronickel are shown in Table 14.

Table 14. Impurities in ferronickel [29]

Smelter	Crude Fe – Ni, %				Refined Fe – Ni, %			
	C	S	Si	P	C	S	Si	P
SLN	2.5	0.40	1.50	0.150	0.03	0.02	0.02	0.02
Cerro Matoso	0.17	0.45	1.45	0.024	0.03	0.03	0.70	0.03
Falcondo	0.02	0.15	0.04	0.030	0.06	0.08	0.30	0.01

Crude ferronickel produced by the conventional rotary kiln – electric furnace process usually contains high levels of carbon and sulfur. These ferronickels are first treated under reducing conditions to remove sulfur and are then refined sequentially under oxidizing conditions with suitable fluxes to remove carbon, silicon, and phosphorus. Ferronickel produced by the selective reduction processes, such as the Ugine or Falcondo processes, which typically contain very low levels (< 0.04 %) of carbon and silicon, are normally treated first for phosphorus and then for sulfur removal. The Falcondo ferronickel is not refined to remove carbon or silicon, and in fact the levels of these impurities increase during refining.

A variety of equipment is used for the refining of ferronickel, including electric arc furnaces, shaking ladles, and low-frequency induction furnaces for desulfurization, and oxygen-blown converters (both L-D and side-blown) for silicon, carbon, and phosphorus removal. The ASEA – SKF ladle furnace, which incorporates an electric arc furnace roof carrying three carbon electrodes and induction stirring of the melt, is used in a number of plants including Cerro Matoso and Falcondo.

Sulfur is generally removed under reducing conditions by adding soda ash, lime, or calcium carbide to the molten ferronickel. Good agitation of the melt is essential to ensure effective mixing of the reagent with the metal phase, and this can be achieved by adding the reagent to the ladle during furnace tapping, by using a shaking ladle, or by providing electrical induction stirring. In some plants poling with greenwood poles is used to provide additional agitation and reductant. Sulfur reacts with the fluxes to form sodium or calcium sulfides, which are slagged off with the silicates formed by reaction of flux with silicon:

$$3\,Na_2O + 2\,S + Si \rightarrow 2\,Na_2S + Na_2SiO_3$$

$$CaC_2 + S \rightarrow CaS + 2\,C$$

The melt cools during this treatment and oxygen is blown into the melt to reheat it to tapping temperature. Two stages of fluxing are often necessary to desulfurize the ferronickel to the required level (0.02 %). The Falcondo smelter uses a complex combination of ferrosilicon, aluminum, silicocalcium, lime, and fluorspar to desulfurize its low-carbon ferronickel.

Removal of silicon, carbon, and phosphorus is normally conducted in an oxygen-blown converter or an oxygen lanced ladle. Carbon is removed simply by oxidation with oxygen to carbon monoxide. Silicon is removed by oxidation with oxygen and fluxing with lime and fluorspar. Phosphorus is oxidized either by blowing the melt with oxygen or by adding iron ore and fluxing the phosphorus(V)oxide with lime:

$$6\,P + 5\,Fe_2O_3 + 12\,CaO \rightarrow 10\,Fe + 3\,Ca_4P_2O_9$$

The slags are removed by skimming after each refining step. If necessary the ferronickel can be deoxidized by addition of ferrosilicon, although this practice increases the silicon content.

Ferronickel is not usually treated to remove cobalt, copper, or arsenic, which may be present in significant amounts. Refined nickel can be produced by the electrorefining of 90 % ferronickel in a chloride – sulfate electrolyte, but this process has not found wide application [98].

8.3. Smelting to Nickel Matte

Low-iron nickel sulfide matte has long been produced from oxide nickel ores by reduction and sulfidization in a blast furnace. This process is still practiced in the former Soviet Union at three smelters in the Urals, but the blast furnace has given way to the electric furnace smelting process in New Caledonia and in the P. T. Inco operation in Indonesia.

8.3.1. *Blast Furnace Smelting*

The blast furnace production of nickel matte was practiced by SLN at its Doniambo smelter in New Caledonia from 1880 until 1972. The nickel silicate ore was blended with calcium sulfate and coke and reduced directly to matte in the blast furnace. The low-grade furnace matte was then blown to 78 % Ni and 20 % S in a converter [91].

At the Yuzhuralnikel Combine at Orsk in the former Soviet Union, nickel silicate ores, averaging 1.02 % Ni, 15.4 % Fe, 10 % MgO, and 49 % SiO_2, are blended with ground coke, limestone, pyrite (0.1 % Cu content), and recycled converter slag and sintered at 1100 – 1200 °C in one of five 75 m^2 downdraft sinter machines. The resulting sinter is crushed and smelted in one of eleven low (5 m height) shaft furnaces using 24 % oxygen enriched air. The furnace matte, containing 17 % Ni, 54 % Fe, and 21 % S is tapped at 1200 °C and blown in Peirce – Smith converters to a high-grade matte (77 % Ni, 2.5 % Cu, 0.2 % Fe, 21 % S).

The converter slag is cleaned to reduce its nickel and cobalt contents in a two-stage contact with molten furnace matte, and

the cleaned slag is recycled to the shaft furnaces. The converter matte is cast, ground, and roasted in fluidized-bed roasters to eliminate sulfur and is then treated in a chloridizing roast in a rotary kiln, followed by acid leaching to remove copper. The leached nickel oxide is reduction smelted with coke and the metal is granulated. The Orsk combine produces 16 000 t/a of nickel granules analyzing 98.5 % Ni, 0.5 % Co, 0.5 % Cu, and 0.5 % Fe from its exceptionally low-grade nickel laterite ore feed [49].

8.3.2. *Matte Production from Ferronickel*

SLN now produces nickel matte from crude ferronickel (24 % Ni + Co, 69 % Fe, 2 % C, and 0.25 % S) by means of a sulfidizing treatment with elemental sulfur in a Peirce – Smith converter [100]. After sulfidizing, the matte is blown with air to oxidize iron, which is slagged off with silica flux in two stages, to produce a matte containing 75 – 80 % Ni, 0.1 to 4 % Fe, and 20 % S. The cobalt content ranges from 0.4 % in matte containing 0.1 % Fe, to 1.2 – 1.7 % Co in matte containing 4 % Fe. This matte is shipped to the SLN nickel refinery at Le Havre-Sandouville in France, where it is refined to high-grade electrolytic nickel. Cobalt is recovered separately in the refining process.

8.3.3. *The Inco Selective Reduction Smelting Process [101-105]*

Inco's process for the production of nickel matte from laterite ores was developed for projects in Indonesia and Guatemala which started operation in 1977. The ore is dried and then calcined and partially reduced in a rotary kiln at 750 – 800 °C. Reduction is accomplished by adding coal to the kiln feed and by lancing high-sulfur oil into the ore bed. The hot calcine is smelted in an electric furnace. The bulk of the sulfur required to form a matte is added as molten elemental sulfur either to the kiln discharge, or directly to the electric furnace discharge. The resulting furnace matte is finally upgraded to the product matte in an air-blown converter.

In the P.T. Inco Indonesia operation on the island of Sulawesi, two ore types are blended to maintain a SiO_2/MgO ratio of 1.9 : 1, and the moist ore is crushed and screened (Fig. 23). The oversize ore is rejected and the fines, which typically contain 2.0 % Ni, 19.3 % Fe, 17 % MgO, and 33.3 % SiO_2 are dried to 20 % moisture. The dried ore is fed to one of three 100-m long rotary kilns, each of which is divided into three zones, for calcining, sulfidizing, and reduction. Reduction is achieved by injecting high-sulfur oil into the hot calcine at the discharge end of the kiln. The combustible cracking products of the injected oil are burned gradually as they pass along the kiln, countercurrent to the ore, by injecting controlled amounts of combustion air. The calcine is discharged at 770 °C and is transferred to one of three 45 MVA electric smelting furnaces. Power for the smelting furnaces is supplied from a captive hydroelectric facility, which has proved a major economic advantage in comparison with most other nickel laterite operations, which are heavily dependent on the use of fossil fuels. Energy consumption in smelting is 2.1 – 2.2 GJ/t ore (580 – 600 kWh/t). Tapping temperatures are 1360 °C for the 32 % Ni, 10 % S matte and 1550 °C for the slag, which typically contains 0.16 % Ni, 20 % Fe, 45 % SiO_2, and 23.5 % MgO.

Figure 23. Flow sheet of the P.T. Inco Indonesia matte smelter

a) Drying kiln; b) Reduction kiln; c) Dried ore storage; d) Top-blown rotary converter; e) Electric furnace (melting); f) Peirce – Smith converter

The furnace matte is upgraded to converter matte (79 % Ni, 19.5 % S, 0.5 % Fe) in one of two side-blown Peirce – Smith converters. These converters were installed to replace the top-blown rotary converters originally provided for this purpose, which had proved to be expensive to operate due to high refractory wear and high maintenance costs. The matte is granulated for shipment to the Japanese market.

The P.T. Inco Indonesia operation is to be expanded from its 1988 production rate of 34 000 t/a Ni to 47 000 t/a Ni in the early 1990s. A smaller Inco operation in Guatemala (Exmibal) which utilized the same process, but was dependent on fuel oil for power generation, closed in 1980 after three years of uneconomic operation.

8.4. Energy Consumption in Laterite Smelting

The pyrometallurgical production of ferronickel and nickel matte from oxide ores is extremely energy intensive and energy costs can account for 50 % of the production cost of ferronickel. Energy is consumed in drying the moist ore, in calcining the dried ore to remove chemically bound water, in heating the charge to melting temperature, and in smelting. Typical fuel and electrical energy consumption data collected in a 1986 survey [30] are presented in Table 15.

Table 15. Smelter fuel and power consumption data [30]

Operation	Ore grade, % Ni	Fe – Ni grade, % Ni	Coal, t/t Ni	Oil, 10^3 L/t Ni	Gas, m^3(STP)/t Ni	Electricity, GJ/t Ni
Falcondo	1.75	38		15.7		
P.T. Inco	2.25	matte	1.1	6.9		140
Hyuga	2.4	20 – 25	7.5			115
Nippon	2.4	20	6.0	0.6		79
Aneka Tambang	2.25	25	2.3	3.8		108
Cerro Matoso	2.9	45	2.7		3.1	94

These figures reflect the trend to the use of coal in preference to oil in the decade following the increase in oil prices in 1973. The oil consumption reported for the Falcondo operation includes both the naphtha used in the metallurgical process and the heavy oil used for the production of electrical power in the on-site generating station.

The distribution of energy consumption in a typical ferronickel smelter is illustrated by the following data (in GJ/t ore):

Drying	1.3 – 2.0
Preheating and prereduction	3.3 – 4.2
Electric smelting	1.4 – 2.2
Other electrical energy	0.22 – 0.29
Total	6.22 – 8.69

Electrical energy for the electric furnace actually accounts for only 25 – 30 % of the total energy consumption in a smelter, while the rotary kiln operation consumes about 50 % of the total energy required.

Total energy consumption at the P. T. Inco Indonesia operation was decreased from 620 GJ/t Ni in 1980 to 460 GJ/t Ni in 1985 by continuing process optimization [103]. During this period the percentage of energy provided by fuel oil was also decreased from 73 % to 62 % of the total by a partial substitution of oil by coal, which provided 8 % of the energy used in 1985. Overall, therefore, these changes resulted in a 37 % reduction in oil consumption per tonne of nickel produced. These economies in fuel oil usage, combined with a low cost source of hydroelectric power, have made the P. T. Inco operation in Indonesia one of the world's cheaper nickel producers [104].

[Top of Page]

9. Hydrometallurgy of Oxide Ores [1], [63]

The chemical and mineralogical homogeneity of limonitic nickel ores, allied with the high value of potential byproducts such as cobalt, chromium, and iron, make them ideal feed materials for hydrometallurgical treatment. Most of the nickel in iron-rich laterite ores is contained in goethite (α-FeO · OH), while the cobalt is almost always associated with manganese oxides. The recovery of nickel and cobalt thus essentially consists of separating them from iron and manganese.

A variety of potential hydrometallurgical or combined pyrometallurgical – hydrometallurgical process routes have been proposed for laterite treatment. Approaches considered include sulfate or chloride roasting followed by water leaching to recover solubilized nickel and cobalt sulfates or chlorides, with soda roasting of the residue and water leaching to recover chromium, as well as the direct leaching of nickel and cobalt with sulfuric, nitric, or hydrochloric acid. Only two hydrometallurgical treatment processes have been commercialized, and although both recover cobalt and nickel, neither is operated for chromium or iron recovery. The two commercial processes, the Caron process, in which partially reduced ore is leached in ammoniacal solution, and the Moa Bay process, using direct sulfuric acid pressure leaching of ore, were both developed to treat the very large, high-iron laterite deposits of Cuba.

9.1. The Caron Process

The reduction roast and ammonium carbonate leach process was patented by M. H. CARON in 1924, but the first commercial application of the process was not initiated until World War II, when a plant was constructed at Nicaro, Cuba. The ore is first dried to about 5 % moisture and is then selectively reduced in a multihearth roaster. The reduced calcine is cooled under nonoxidizing conditions and leached in ammoniacal ammonium carbonate solution to selectively extract nickel and cobalt. The pregnant leach liquor is then boiled to strip ammonia and carbon dioxide, causing the nickel and cobalt to precipitate as basic carbonates. The mixed nickel – cobalt basic carbonate can be calcined to a nickel oxide product or can be refined to nickel powder or cathode. Details of a number of operations using the Caron process are given in Table 16.

Table 16. Commercial Caron process plants

Operation	Design capacity, t/a Ni	Feed ore, %		Product type
		Ni	Co	
Nicaro, Cuba	22 500	1.40	0.10	NiO sinter
Queensland Nickel, Australia	18 000	1.35	0.11	NiO rondelles, NiS – CoS
Nonoc, Philippines	30 000	1.22	0.10	Ni powder, NiS – CoS
Punta Gorda, Cuba	30 000			NiO sinter
Tocantins, Brazil	5 000	1.60	0.14	Ni cathode
Elbasan, Albania	3 000			$NiCO_3$

The original plant at Nicaro, built and operated by the Freeport Sulfur Company [1], [86], for the U.S. Government, was

commissioned in 1944. It was closed down in 1947 as uneconomic under peacetime conditions, despite having achieved a production rate of 14 500 t of nickel as nickel oxide in 1946. However nickel recovery from the ore had never exceeded 70 %. It was reopened in 1952 for the U.S. Government under the operating management of a joint venture of the National Lead Company and Fomento de Minerales Cubanos. Its production capacity was increased to 22 500 t/a Ni in 1957, and in 1960 it was nationalized by the Cuban Government. Production is believed to have ranged from 16 000 – 20 000 t/a Ni during the 1970s and 1980s [106].

Freeport was also a member of the joint venture which constructed the Queensland Nickel refinery near Townsville, Australia in 1974, which drew heavily on the design and operating experience gained at Nicaro [107]. A second Caron plant in Cuba was built by the Cuban Government with Soviet assistance in the early 1980s at Punta Gorda, near Moa Bay. The first of three processing lines was commissioned in 1986 and by the end of 1988 production was reported to have reached 10 000 t/a Ni as nickel oxide. A third Cuban Caron plant is under construction in the same area at Las Camarioca, scheduled to start-up in 1995 [108].

The other large Caron plant was built by Marinduque Mining and Industrial Corporation on Nonoc Island in the Philippines with technical assistance from Sherritt Gordon [109], [110]. The Nicaro process was adapted by Sherritt to increase nickel and cobalt extractions and to produce hydrogen-reduced powder from the basic nickel carbonate. The Nonoc nickel refinery was commissioned in 1974 and reached a production rate of around 22 000 t/a Ni in 1977, at a nickel recovery of 78 % Ni. This plant was closed in 1986 after several years of declining operation due to adverse economic conditions. There are currently (1989) plans to refurbish the process plant and resume operation in the early 1990s. Both the Queensland Nickel and the Marinduque nickel operations were designed to recover cobalt separately as a byproduct by precipitating a mixed cobalt – nickel sulfide prior to precipitation of basic nickel carbonate.

The Companhia Niquel Tocantins plant in Brazil began production of nickel cathode from basic nickel carbonate in 1981 and was scheduled to increase capacity to 10 000 t/a Ni by 1990 [111]. The small Caron plant at the Elbasan metallurgical complex in Albania ships its basic nickel carbonate product to the Severonikel Combine in the former Soviet Union for refining to metal.

Industrial practice is illustrated by the following description of the Queensland Nickel process, which closely resembles the original Nicaro process [1] except for the addition of a cobalt recovery step. The flow sheet of this plant, which was designed to treat 5700 t/d of ore from the Greenvale ore body is outlined in Figure 24 [107], [63].

Figure 24. Flow sheet of the Queensland Nickel laterite refinery

CCD = Countercurrent decantation; BNC = Basic nickel carbonate

The blended ore (1.35 % Ni, 0.11 % Co, 25 % Fe, 10 % MgO) is first dried in one of three rotary dryers to about 5 % moisture content. The dried ore is then ground in a ball mill and blended with fuel oil as a reductant, before being fed to one of ten seventeen-hearth Herreschoff roasters, where it is roasted under reducing conditions at 700 – 760 °C with a retention time of ca. 90 min. The ore is heated by hot reducing gas ($CO + H_2$) formed by the combustion of fuel oil in a deficiency of air in the ten combustion chambers on each roaster. The reduction potential of the gas phase is regulated so that most of the nickel and cobalt in the ore are reduced to the metallic state (as a ferronickel alloy) and the iron(III) oxides are reduced to magnetite without significant reduction of the iron oxides to iron(II) oxide or to the metal.

$$NiO + H_2 \rightarrow Ni + H_2O$$

$$3\,Fe_2O_3 + H_2 \rightarrow 2\,Fe_3O_4 + H_2O$$

As a result the nickel and cobalt are rendered amenable to ammoniacal leaching while the iron remains as insoluble oxides or silicates. Typically 80 – 85 % of the nickel content of the ore is converted to the metallic form. Any nickel oxide which is not reduced to metal is rendered insoluble under the roasting conditions by incorporation into the silicate minerals. Good control of the roasting conditions is therefore essential for optimal nickel recovery in the process.

The reduced ore is cooled in a nonoxidizing atmosphere, to avoid reoxidation of the nickel, and is quenched and leached in ammoniacal ammonium carbonate solution containing 7 % NH_3 and 4 % CO_2. Leaching is carried out in three trains of four mechanically agitated, air-sparged leaching tanks at a pulp density of ca. 20 % solids. The leaching reactions can be represented by the following equation:

$$FeNi + O_2 + 8\,NH_3 + 3\,CO_2 + H_2O \rightarrow Ni(NH_3)_6^{2+} + Fe^{2+} + 2\,NH_4^+ + 3\,CO_3^{2-}$$

The iron(II) is further oxidized and precipitates as iron(III) hydroxide:

$$4\,Fe^{2+} + O_2 + 2\,H_2O + 8\,OH^- \rightarrow 4\,Fe(OH)_3$$

However, significant losses of cobalt occur by coprecipitation with the iron hydroxide.

The pregnant liquor is separated from the leached ore in a seven-stage countercurrent decantation thickener circuit using ammoniacal solution as the washing medium. The washing efficiency is typically 99 %. Ammonia is recovered from the washed leach residues by steam stripping, and the barren solids are discarded. The pregnant liquor recovered from the wash

circuit, which contains 10 g/L Ni and 0.5 g/L Co, was formerly treated with ammonium hydrogen sulfide in a pipeline reactor to precipitate virtually all of the cobalt and about 10 % of the nickel. The mixed sufide product (15 % Co, 40 % Ni) was thickened, washed, and spray dried, and sold for cobalt and nickel recovery elsewhere. Ammonia and carbon dioxide were then stripped from the cobalt-free solution by direct stream injection to precipitate basic nickel carbonate.

Since 1988, the pregnant liquor has been treated by solvent extraction to separate nickel and cobalt [112]. An organic reagent (LIX 87 QN) is used to extract nickel selectively from the pregnant liquor. The nickel is recovered from the solvent by stripping with a more concentrated ammoniacal ammonium carbonate solution. Basic nickel carbonate can then be precipitated from the strip liquor by steam injection to remove ammonia and carbon dioxide. Copper sulfide is precipitated from the raffinate and refined elsewhere.

The basic nickel carbonate is recovered by thickening and filtration, and the wet filter cake, containing about 50 wt % moisture, is dried and calcined at 1300 °C in an oil-fired rotary kiln to yield nickel oxide. The nickel oxide calcine (77 % Ni) is upgraded by partial hydrogen reduction to yield nickel oxides containing 85, 88, or 90 % Ni, which are compacted to rondelles and sintered for market.

By the late 1980s the Greenvale nickel ore body, which had provided the sole feed to the Queensland Nickel refinery since 1974 was rapidly becoming depleted, and the operation started to treat laterite ores imported from New Caledonia and Indonesia.

The major difference between the process flow sheets used by Queensland Nickel and Marinduque / Nonoc was the production of refined nickel powder in the latter [110]. Basic nickel carbonate was redissolved in ammoniacal ammonium sulfate solution and metallic nickel powder was precipitated by reduction with hydrogen under pressure at 200 °C (Section Hydrogen Reduction to Nickel Powder). The nickel powder typically analyzed 99.8 % Ni, 0.08 % Co, 0.01 % Fe, 0.007 % Cu, 0.006 % C, and 0.004 % S. By comparison the nickel oxide sinter produced prior to 1960 in the Nicaro plant, which had no cobalt separation step, analyzed 88 % Ni, 0.7 % Co, 0.04 % Cu, 0.3 % Fe, 0.05 % C, 0.05 % S, and 7.5 % O_2. In the Tocantins refinery a crude basic nickel – cobalt carbonate is redissolved in spent sulfuric acid electrolyte, and after purification by sulfide precipitation to remove cobalt and copper, the solution is treated by electrowinning to yield nickel cathode [63].

The Caron process is very energy intensive, and this factor proved a major economic handicap for the Queensland Nickel and Marinduque/Nonoc plants, which were both designed prior to 1973, with their heavy reliance on fuel oil for ore drying, reduction, and power generation. The fossil fuel energy requirements for the process for ore drying and reduction, and power and steam generation amount to ca. 6.7 GJ/t of dry ore, with an additional 200 – 250 MJ/t of electrical power.

The Queensland Nickel plant originally consumed 900 t/d of fuel oil to treat 5700 t of ore. The distribution of oil consumption is as follows [113]:

Ore drying	14 %
Steam and power generation	35 %
Ore reduction roasting	47 %
Nickel carbonate calcining	4 %

Both Queensland Nickel and Marinduque/Nonoc converted their ore drying and steam and power generation facilities to use coal in place of oil in the early 1980s, with substantial economic benefit. However, conversion of the roasters to coal firing was not considered to be technically feasible. The Tocantins plant in Brazil makes extensive use of local eucalyptus wood as fuel in its ore treatment plant.

9.2. Pressure Leaching with Sulfuric Acid [1]

Because of the naturally high moisture content of limonite minerals (20 – 50 % H_2O), it would be advantageous if the ore drying and reduction roasting steps, which together account for over 50 % of the energy consumed in the Caron process, could be avoided, and the ore leached directly. However direct attack by the common mineral acids under ambient conditions is unselective and total dissolution of the ore results, with uneconomically high acid consumption. Fortunately, leaching of the ores in sulfuric acid at high temperature (> 250 °C) and pressure is highly selective since nickel and cobalt are stable as soluble sulfates, while iron(III) sulfate hydrolyzes and precipitates as a hydrated iron(III) oxide. Offsetting the energy savings in this type of process are the increased costs of construction materials capable of withstanding the highly corrosive environment of the high-temperature acid leach.

The applicability of the acid leach process is limited to those ores which do not contain substantial levels of other acid consuming minerals such as magnesia. It was for this reason that Freeport did not select an acid leaching process when seeking a process to treat the Nicaro ores (8 % MgO). However when the same company subsequently developed the low-magnesia (1.7 % MgO) limonitic ore body at Moa Bay, Cuba, the sulfuric acid leach process was selected since it offered much higher (90 % or more) recoveries for both nickel and cobalt, with relatively low acid consumption. Although this process has been applied on a commercial scale only in the one plant at Moa Bay, considerable process development effort was devoted during the 1970s to improving the economics and extending the applicability of the process to higher magnesia content ores, principally by Amax.

9.2.1. *The Moa Bay Process*

The plant at Moa Bay was designed and built by Freeport in 1959 to produce 22 700 t/a Ni and 2000 t/a Co in the form of a mixed sulfide concentrate. The concentrate was to be refined to the pure metals in a separate plant which Freeport built at Port Nickel, Louisiana, where a cheap supply of natural gas was available. The Moa Bay operation was nationalized in 1960

by the Cuban Government before construction was complete. It was recommissioned in mid-1961 with Soviet assistance, and since then the nickel – cobalt sulfide concentrate has been shipped to the former Soviet Union for further processing. The current production rate (1988) is believed to be 18 000 t/a Ni and 1600 t/a Co.

Although the original plant design is well documented, information on subsequent modifications is fragmentary. The following description is therefore based largely on accounts dating from 1960 [1], [106], [114-116]. The process flow sheet is shown in Figure 25. The ore, which consists mainly of goethite (α-FeO · OH), is slurried in water and screened to remove low-grade, oversize material, which is discarded. The fines fraction (< 1 mm) that forms the feed to the acid pressure leach averages 1.35 % Ni, 0.15 % Co, 48 % Fe, 1.7 % MgO, 9 % Al_2O_3, 3 % Cr_2O_3, and 4 % SiO_2 in composition. It is leached at 45 % solids pulp density with 98 % sulfuric acid (240 kg H_2SO_4/t dry ore) at about 245 °C and 4.3 MPa, with a retention time of 1 – 2 h. The acid is made on-site from elemental sulfur, and the waste heat from the acid plant is used in the leaching circuit. Leaching is carried out in four leaching trains each containing four large vertical autoclaves, which are lead- and brick-lined with titanium internal fittings. Agitation is achieved by injecting high-pressure steam into a draft tube at the bottom of the vessel. Heat is recovered from the autoclave discharge slurry for use in preheating the cold feed slurry. Under these conditions, about 94 % of the nickel and cobalt dissolve, while iron solubility is limited to about 1 g/L.

$$NiO + H_2SO_4 \rightarrow NiSO_4 + H_2O$$

$$CoO + H_2SO_4 \rightarrow CoSO_4 + H_2O$$

The leach liquor typically contains 6 g/L Ni, 0.5 g/L Co, 2 g/L Mn, 0.8 g/L Fe, 0.4 g/L Cr, 2.5 g/L Mg, 2 g/L SiO_2, 3 g/L Al, and 30 g/L H_2SO_4. The liquor is separated from the leach residue (0.08 % Ni, 0.01 % Co, and 51 % Fe) by countercurrent decantation (CCD) washing with water in a six-stage thickener circuit. The washed residue is stockpiled for possible future use as iron ore.

The pregnant solution is treated with coral mud (calcium carbonate) to neutralize the acid and precipitate most of the dissolved iron, aluminum, and manganese by hydrolysis. The precipitated sludge is recycled to the wash circuit and joins the leach residue for disposal. The neutralized solution typically contains (g/L): 3.5 – 4.0 Ni, 0.3 – 0.4 Co, 1.0 Mn, 0.3 Fe, 0.4 Cr, 2.5 Mg, 1.0 SiO_2, and 3.0 Al at pH 2.5.

Nickel and cobalt are recovered from solution in 98 – 99 % yield by precipitation at 120 °C with hydrogen sulfide at a pressure of 1.1. MPa in a three-compartment, brick-lined autoclave.

$$NiSO_4 + H_2S \rightarrow NiS + H_2SO_4$$

The barren solution typically contains (g/L): 0.05 Ni, 0.01 Co, 1.0 Mn, and 7 H_2SO_4. The nickel – cobalt concentrate contains 55 % Ni, 5 % Co, 0.7 % Fe, 0.2 % Cu, 1.0 % Zn, and 35 % S.

The refinery built by Freeport in Louisiana to treat the concentrate employed pressure hydrometallurgy and hydrogen reduction to separate and refine nickel and cobalt. This plant was being commissioned when the Cuban nickel industry was nationalized in 1960, and was never used for the purpose for which it was designed. Currently (1989) the total nickel – cobalt concentrate production from Moa Bay is shipped to the former Soviet Union, where it is treated at a smelter in the Urals to produce nickel – cobalt anodes analyzing 87 % Ni, 8 % Co, 2 % Fe, and 0.7 % Cu. The anodes are electrorefined at the Yuzhuralnikel Combine at Orsk in a conventional sulfate – chloride electrolyte system. The nickel is recovered as high-grade electrolytic nickel, and cobalt is separated from anolyte by chlorine precipitation (Section Electrorefining) for subsequent processing to metal [49].

Energy consumption in the Moa Bay acid leach process is relatively low because over half the steam requirement for the leach is provided by waste heat recovered from the sulfuric acid plant. The fuel oil requirement for the generation of power and steam has been estimated at about 40 kg/t of dry ore, which is only 20 % of the fuel requirement for the Caron process. However, this energy benefit is frequently outweighed by the high consumption of sulfuric acid which depends directly on the magnesia content of the ore [117].

9.2.2. *The Amax Acid Leach Process [118-120]*

The Amax acid leach process for the treatment of laterite ores was developed, on the basis of the Moa Bay process, with the object of increasing metal recoveries while decreasing acid and energy consumption. The process was tested extensively in pilot plant and prototype plant campaigns between 1975 and 1981, for a potential new project in New Caledonia which was subsequently abandoned.

In the Amax process (Fig. 26) the ore is divided by selective mining or screening into a low-magnesia limonitic fraction and a smaller fraction of high-magnesia serpentinic ore. The finer limonitic fraction is leached directly in the pressure leach at 270 °

C, while the high-magnesia fraction is first calcined and then preleached at atmospheric pressure with the leach liquor from the countercurrent decantation wash circuit, before it goes to the pressure leach. Essentially stoichiometric utilization of the acid is achieved by this countercurrent leaching of the high-magnesia ore. The overall acid requirement is thus reduced substantially, and the need for a separate alkaline neutralizing agent (e.g., coral mud at Moa Bay) is eliminated. Metal extractions of 94 – 97 % are normally achieved with a 20-min retention time in the pressure leach at 270 °C.

Figure 26. Flow sheet of the Amax nickel laterite process

A major saving (up to 70 %) in energy consumption in the leaching step is achieved by using indirect heating of the feed slurry with flash steam recovered from the autoclave discharge slurry. By using this technique in place of direct steam sparging, the concentration of metals in solution is substantially increased, and the size and cost of subsequent processing steps is reduced. Overall the requirement for fossil fuel is estimated to be only 50 % of that for the Moa Bay operation. A further simplication of the process was achieved by improving mass transfer in the sulfide precipitation step so that it could be operated at a lower pressure of 0.2 MPa compared with 1.1 MPa at Moa Bay. The Amax acid leach process is claimed to be economically viable over a wide range of laterite ore compositions, with magnesia contents as high as 15 % MgO.

[Top of Page]

10. The Recovery of Byproduct Cobalt

All nickel ores, whether sulfide or oxide, contain significant amounts of cobalt that can potentially be recovered as a valuable byproduct. Overall, however, the recovery of cobalt from nickel ores is very low, and the nickel industry provides less than 30 % of world cobalt production. The greater part of world cobalt production arises from the copper operations in Zaire and Zambia.

No cobalt recovery at all is possible in ferronickel smelting, where the cobalt is distributed between the discard slags and the ferronickel product, in which it merely represents an impurity. The same comments apply to class II nickel products such as nickel oxide sinter, made by the smelting of sulfide concentrates or by the Caron process without a cobalt separation circuit.

Cobalt is normally recovered in high yield as a byproduct of carbonyl, electrolytic, or hydrometallurgical refining of nickel metal or matte. However, even in these cases the overall recovery of cobalt from the ore is low, since most of the cobalt is lost to the slag phase in the prior smelting processes. Cobalt recovery in the converting operation depends critically on the final iron content of the matte. Typically if the matte is blown to less than 1 % Fe, over 75 % of the cobalt reports to the slag phase and is effectively lost. If the conversion process is stopped at 3 – 5 % Fe, however, over 75 % of the cobalt remains in the matte, and can be recovered during subsequent refining.

In practice few nickel smelters are operated to maximize the recovery of cobalt. The SLN in New Caledonia and the Soviet smelters producing matte from laterites are notable exceptions. Slags are cleaned by contact with a high-iron matte, which becomes enriched in cobalt. The cobalt is then recovered by hydrometallurgical treatment of the enriched material.

Even in the ammonia pressure leaching of nickel sulfide concentrates, where the smelting step is bypassed, cobalt recovery is much lower than that of nickel, due to a strong affinity of the iron oxide residue for soluble cobalt. Probably the highest overall recovery of cobalt from nickel ores is achieved in the sulfuric acid pressure leaching of laterite ores, in which a cobalt recovery of 90 % is possible.

[Top of Page]

11. Nickel Recovery from Secondary Sources

Nickel-containing scrap from forming processes in fabricating plants and machine shops is an important source of feed material for the production of nickel-containing stainless steel. Typically, in the United States about 40 % of the nickel used for stainless steel production is provided in the form of stainless steel scrap from outside sources. Recycled inhouse scrap is not included in this estimate [121], [122]. Nickel-containing scrap falls mainly into the categories of stainless steels, superalloys, copper – nickel alloys, and nickel itself. Usually scrap is recycled to a plant which produces the same type of alloy.

Inco established The International Metals Reclamation Company (INMETCO) at Ellwood City, Pennsylvania in 1978, to collect and convert nickel-containing waste materials from specialty steel companies into a stainless steel remelt material. This 40 000 t/a capacity plant treats various grades of scrap materials including flue dusts, scale and turnings, as well as stainless steel scrap, to produce 23 kg remelt pigs containing ca. 18 % Ni and 8 % Cr [123]. Falconbridge also started to recycle nickel- and cobalt- containing alloys to its primary nickel smelter in 1985 [124].

[Top of Page]

12. Market Products

Unlike copper, nickel is rarely used without further processing and so the mechanical or physical properties of nickel products are of no significance, and nickel is marketed solely on the basis of its chemical composition. Nickel is marketed according to its chemical purity as either a Class I or a Class II product. Class I includes the high-purity products, electrolytic cathode, carbonyl refined granules and powder, and hydrogen-reduced nickel in powder or briquette form. Commercial nickel of this

class is normally 99.7 % pure or better [125].

Class II includes the various grades of ferronickel, nickel oxide, and metallized nickel oxide. Typical compositions for Class I and II products are given in Table 17. Class II nickel products, which normally sell at a discount to Class I nickel, became more popular during the 1970s, since the new stainless steel making techniques such as the AOD process can tolerate higher impurity levels in the feed materials. However this trend was reversed during the 1980s, during the period of oversupply and low metal prices, particularly for alloy steel production where Class I nickel was preferred [122].

Table 17. Commercial forms of nickel [125]

Type	Composition, %						
	Ni	Co	Cu	Fe	C	S	O
Class I:							
Cathodes	> 99.90		0.005	0.002	0.01	0.001	
Pellets	> 99.97	5×10^{-5}	0.001	0.0015	< 0.10	0.0003	
Powder	99.74			< 0.10	< 0.10	< 0.010	< 0.15
Briquettes	99.90	0.03	0.001	0.01	0.01	0.0035	
Rondelles	99.25	0.37	0.046	0.022	0.022	0.004	0.042
Class II:							
Ferronickel	20 – 50	1 – 2		rest	1.5 – 1.8	< 0.3	
Nickel oxide	76.0	1.0	0.75	0.30		0.006	rest

Some nickel products are designed for specific applications, such as the 0.02 % S content “S Nickel Rounds” produced by Inco as “active” anode material for the plating industry, and the special powders used in Ni – Cd batteries. Traditionally, electrolytic nickel cathodes are cut into 2.5 cm squares for market. Both the major producers of electrolytic nickel, Inco and Falconbridge, now produce electrolytic nickel in the form of “rounds” (Inco) or “crowns” (Falconbridge), by plating nickel onto specially masked cathode blanks, to produce discrete round deposits. These deposits can be stripped from the blanks and drummed directly without shearing, and are easier for the consumer to handle than sheared cathode.

[Top of Page]

13. Uses [122], [126-128]

The major first uses of nickel are summarized in Table 18. Stainless steel production accounts for over 50 % of nickel consumption, followed by ferrous alloys, and nickel-base alloys. Electroplating takes only 11 % of nickel consumption [129].

Table 18. Western-world nickel consumption: distribution by first use in 1987 [129]

First use	Distribution, %
Stainless steel	51
Alloy steels	12
Nickel-base alloys	15
Copper-base alloys	3
Plating	11
Foundry	5
Other	3

A more detailed breakdown of nickel consumption by end use is given in Table 19. The consumer product category, which includes the stainless steel used in kitchen sinks, laundry equipment, furniture and tableware, as well as nickel-plated parts for bicycles, motorcycles, jewelry, eyeglass frames, and musical instruments, accounts for one quarter of nickel consumption. The high strength of nickel stainless steels combined with light weight and low maintenance have contributed to their growing use in railway cars and road tank trailers in the construction and machinery category [128].

Table 19. Western-world nickel consumption: distribution by end use in 1987 [129]

End use	Distribution, %

Consumer products	25
Construction and machinery	13
Automotive industry	11
Chemical industry	9
Building and construction	6
Process industry	6
Electronics	6
Power industry	5
Petroleum industry	5
Aerospace	3
Nickel chemicals	2
Marine applications	2
Coinage	2
Other	5

Nickel consumption dropped significantly during the 1970s in the automotive industry with the amount of nickel used in the average U.S. car falling from about 2 kg in 1970 to only 0.5 kg by 1985 [122]. The chemical industry is the fourth largest market for nickel, mainly in stainless steels for a multitude of applications.

Building and construction, the process industries, and the electronics industries each accounted for about 6 % of nickel consumption in 1987. Stainless steel usage in architectural applications is increasing, as it is in environmental control equipment and food processing equipment. The growth rate of nickel usage in the electronics industry is greater than 10 % per annum. Alloy 42, a nickel – iron alloy, is widely used in lead frames, while a copper – nickel – tin alloy C72500, is used in springs, clips, and terminals.

In the power industry, nickel-containing stainless steels are widely used in nuclear power stations and are increasingly being applied in scrubber systems for the removal of sulfur dioxide from the flue gases of oil- and coal-fired power stations. Nickel-containing materials are used in the petroleum industry in applications ranging from drilling bits to piping and process vessels in petrochemical plants, and to the construction of off-shore production platforms. In the marine category, nickel-containing materials are used in ships and in desalination plants. In the aerospace industry nickel is a key element in superalloys that resist stress and corrosion at temperatures of 1000 °C and above. These materials are used in gas turbine engines.

Nickel chemicals are used in the production of nickel catalysts for use in the hydrogenation of vegetable oils, in heavy oil refining, as nickel salts in electroplating, and for color enhancement in ceramics. Coinage alloys containing nickel have been used since ancient times [3]. Today the 75 Cu – 25 Ni cupronickel alloy is the most widely used, although Canada, the Netherlands, and the Republic of South Africa use pure nickel coinage, which is particularly durable.

In 1984, after several years of decreasing world demand for nickel, sixteen of the major nickel producers cooperated to set up the Nickel Development Institute (NiDI) with headquarters in Toronto, Canada. The NiDI has a mandate to increase the use of nickel. In this function NiDI has taken over the market development role which was performed very effectively by Inco from the 1920s until the mid 1970s, when a much reduced share of world nickel production and the depressed nickel market forced Inco to cut its activity in this area. The NiDI, which is international in scope, has set up technical information offices in North America, Europe, Japan, India, and Central and South America, backed by a worldwide network of consultants. The organization publishes a periodical applications oriented magazine, “Nickel”, which has wide circulation, as well as sponsoring technical papers and a series of reference books on selected topics. The NiDI has initiated a wide range of market development and research programs to promote the use of nickel, and provides expertise and advice to users of nickel and nickel-containing products [126], [128].

[Top of Page]

14. Economic Aspects [126], [129]

Western-world nickel consumption increased by an average of 6.5 % per annum from 1945 to 1974, when it reached a level of 576 000 t (Fig. 27). Consumption dropped sharply in 1975, and the demand for nickel remained flat for the next ten years, with annual rates fluctuating in the range 450 000 – 600 000 t/a. Although demand approached the 600 000 t/a consumption level in 1979 it was not exceeded until 1987 [130]. Western-world nickel consumption in 1987, 1988 and 1992 was 625 000 t, 640 000 t and 813900 t, respectively.

Figure 27. Western-world nickel consumption

a) 1949 recession; b) Korean war; c) 1954 recession; d) 1958 recession; e) 1961 recession; f) Vietnam war; g) 1971 recession; h) 1974 – 1976 recession; i) 1980 – 1982 recession

The slowdown in the growth of nickel consumption in the mid 1970s coincided with a major increase in production capacity, when several laterite projects, which had been under development for five to ten years, came on stream. Many of these projects were heavily dependent on fuel oil and in consequence suffered a severe penalty when oil prices increased dramatically in 1973. During this period, nickel production by the Eastern-bloc countries also regularly exceeded consumption

by 15 000 to 40 000 t/a, and substantial exports were made to Western markets.

By 1980 there were over forty nickel producers in 26 different countries, and the nickel price collapsed as the demand for nickel dropped in 1981 and 1982, and the producers fought for the shrinking market. Even the most cost efficient suffered heavy loses, and several higher cost producers were eventually forced to close permanently. The surviving operations sought to cut operating costs in every facet of nickel production, and as a result the nickel industry was much leaner and more cost efficient by the end of the 1980s.

When Western-world stainless steel production increased by 15 % in 1987, the demand for nickel increased by over 10 % from the relatively constant levels of 1984 to 1986. After more than ten years of depressed metal prices and production rates, the industry was unable to respond by increasing production levels since producer inventories of metal had been run down to a minimum and most marginal capacity had been eliminated in the drive to reduce operating costs. The result was a two year period of inflated nickel prices, with the London Metal Exchange (LME) refined nickel cash price, which had averaged US $ 1.60/lb in January 1987, peaking at $ 10.84 in March 1988. The average price for the whole of 1988 was $ 6.25/lb, and high prices continued through most of 1989 with an average price for the year of $ 6.05. This development restored the financial health of the industry after many years of marginal or uneconomic operation.

The high nickel prices of 1988/89 raised concerns among both stainless steel and nickel producers that substitution of nickel-bearing materials by cheaper materials would be encouraged. Average industry operating costs in 1989 were estimated to be around US $ 2/lb, while estimates of the capital expenditure required for a new integrated nickel project range upwards from US $ 10/lb of annual capacity. A long-term nickel price of US $ 4 – 5/lb, which would be needed to justify investment in new production capacity can be expected to depress demand and render new capacity unnecessary. Future increases in production thus appear more likely to come from the expansion of existing operations than from totally new projects.

Details of world nickel mine and smelter production by country for 1985 are given in Table 20 and the corresponding consumption breakdown is shown in Table 21. Table 22 provides a listing of the world's major nickel-producing operations.

* M = mine; S = smelter; R = refinery.

For many years nickel was sold on the basis of posted producer prices, set to a large extent by Inco as the major producer. In 1979 the LME started trading in Class I nickel, and even though the LME handles only a relatively small percentage of total nickel production, it has since become the major factor in determining nickel price levels. Prices are quoted in US $ per metric tonne of Class I metal.

1. Introduction

Nickel forms mixed crystals over a wide range with copper, manganese, iron, chromium, and other metals. It is mainly used as an alloying element in many nonferrous materials and steels (approximately 2000) to improve their strength, toughness, corrosion resistance, and high-temperature properties. About 60 % of the primary nickel produced in the Western World is used in the production of stainless steels, and a further 13 % is used in the production of nickel-base alloys, including pure nickel semi-finished products.

In 1988 primary nickel consumption by first use in the Western World broke down as follows [2]:

Alloy steels	6 %
Stainless steels	60 %
Nonferrous nickel-base alloys	13 %
Plating applications	10 %
Foundry industry	6 %
Other applications	5 %

Nickel alloys have been standardized in most industrial countries. Table 1 lists the most important materials standards in the USA. In the Federal Republic of Germany, the chemical compositions of nickel-base alloys are standardized in:

DIN 17 740	Wrought nickel
DIN 17 741	Wrought nickel alloys (low alloyed)
DIN 17 742	Wrought nickel alloys with chromium
DIN 17 743	Wrought nickel alloys with copper
DIN 17 744	Wrought nickel alloys with molybdenum and chromium
DIN 17 745	Wrought alloys of nickel and iron with other alloying elements

and the mechanical properties in:

DIN 17 750	Plate, sheet and strip of wrought nickel and nickel alloys
DIN 17 751	Tubes of wrought nickel and nickel alloys
DIN 17 752	Rod and bar of wrought nickel and nickel alloys
DIN 17 753	Wire of wrought nickel and nickel alloys

ISO Standards for nickel and nickel alloys have been under negotiation by the industrial national standard organizations for many years. Two basic ISO Standards have been issued so far: ISO 6372-01:1989 “Nickel and Nickel Alloys – Terms and Definitions, Part 1, Materials” and ISO 6372-03:1989 “Wrought Products and Castings”.

The following ISO Standards (still in the form of draft proposals) are expected to be published in 1991: ISO 9721, 9722, 9723, 9724, 9725, 6207, and 6208.

Nickel alloys are mainly used as corrosionresistant materials or for their excellent high-temperature strength or special physical properties. Accordingly, they can be divided into two principal groups:

1) Single-phase, solid-solution alloys that are primarily corrosion resistant at room and elevated temperature. These have face-centered cubic structures, moderate strength, and good weldability. Their applications often depend on specific physical properties.
2) Precipitation hardening alloys, most of which have high-temperature strength and creep resistance (up to 1050 °C). These alloys have a face-centered cubic matrix with precipitations. They have limited weldability (resistance welding or electron beam welding) or are unweldable.

Developments in manufacturing techniques (argon oxygen degassing and vacuum oxygen degassing methods) have enabled new nickel alloys with improved properties to be produced.

Oxide dispersion strengthened alloys with very high creep strengths are manufactured by powder metallurgy.

All nickel alloys may be further alloyed with aluminum, titanium, and/or niobium to render them age-hardenable. The age-hardened, creep-resistant Ni – Cr alloys are of particular importance.

The standard specifications of the United States (Table 1) or the Federal Republic of Germany are used to identify alloys when available; trade names are used to identify newer materials that have yet to be standardized.

The solid solution alloys, which are mostly corrosion resistant, are fusion welded in the construction of equipment, pipework, and vessels by using standardized matching filler metals.

Age-hardenable and oxide dispersion strengthened alloys cannot be fusion welded, and are either resistance welded or joined by using high-temperature nickel-base brazing alloys [1–6].

2. Wrought Nickel

Wrought nickel (DIN 17 740 and ASTM B160, B161, B162, B725, and B730) is used in the construction of equipment and vessels, for electrical and electronic components, and for coins.

The grades covered by DIN 17 740 are listed in Table 2. Weldable grades contain max. 0.02 % C to avoid precipitation of graphite in the heat-affected zones of the welds, as this would have a detrimental effect on strength properties. Pure nickel is ferromagnetic up to its Curie temperature (353 °C). Figure 1 shows the coefficient of thermal expansion of nickel as a function of temperature; other properties are given in [8]. Purity has a great effect on properties. The strength is

Table 2. Wrought nickel grades, standardized in DIN 17 740 [7]

Material		Composition, max %								
Designation	Number	Ni, min.∗	C	Cu	Fe	Mg	Mn	S	Si	Ti
Ni99.6	2.4060	99.6	0.08	0.1	0.2	0.15	0.3	0.005	0.1	0.1
LC-Ni99.6	2.4061	99.6	0.02	0.1	0.2	0.15	0.3	0.005	0.1	0.1

LC-Ni99	2.4068	99.0	0.02	0.25	0.4	0.15	0.3	0.005	0.2	0.1

∗ Includes max. 1 % Co.

Table 3. Tensile properties of plate (up to 50 mm thickness), sheet and strip (up to 2 mm thickness), DIN 17 750

Material designation	Material no.	Tensile strength, MPa	0.2 % Proof strength, MPa	Elongation δ_5, %	Brinell hardness
Ni99.6F370	2.4060.10	370	100	40	max. 100
Ni99.6F490	2.4060.26	490	290	20	ca. 130
Ni99.6F590	2.4060.30	590	490	2	ca. 200
LC-Ni99F340	2.4068.10	340	100	40	max. 100
LC-Ni99F430	2.4068.26	430	150	20	ca. 130
LC-Ni99F540	2.4068.30	540	430	8	ca. 180

low in the annealed condition: elongation and toughness are high (Table 3).

Figure 1. Coefficient of thermal expansion of pure nickel [8]

Since treatment of pure nickel does not produce any structural change, only cold working can increase its strength, the extent of the improvement depending mainly on the carbon content. The increase in strength disappears partly or completely upon recrystallization annealing [7–9].

3. Nickel – Iron Alloys

Nickel-base alloys with iron and other alloying elements (Co, Cr, Cu, and Mo) are solid solution alloys with face-centered cubic lattices. Owing to their physical properties, they are used as soft magnetic materials, as glass-to-metal seals, and as materials with defined thermal expansion properties. The nickel – iron phase diagram (Fig. 2) shows that, above 35 % nickel, the alloy is wholly in the γ-state, in which the magnetic transition has a temperature maximum at about 70 % Ni. The compositions and applications of some typical Ni – Fe alloys are given in Table 4.

Figure 2. Binary phase diagram nickel – iron [12]

As well as the pure nickel – iron alloys, grades with cobalt and chromium additions are used, especially for metal-to-glass seals (Table 4, see next page).

Table 4. Nickel – iron alloys for main applications [12]

DIN designation	Material number [a]	Composition, wt %			
		Ni	Cr	Fe	Others
Soft magnetic alloys					
Ni48	1.3922	min. 46		49 – 53	
NiFe44	2.4420	min. 53		43 – 46	
NiFe10CuMo	2.4520	min. 75		13 – 17	4 – 6 Cu 3 – 5 Mo
NiFe16CuCr	2.4500	min. 75	1.5 – 2.5	15 – 18	4 – 6 Cu
NiFe15Mo	2.4540	min. 78		14 – 17	3 – 5 Mo
Glass-to-metal seals					
NiFe45	2.4472	min. 53		45 – 47	
NiFe46	2.4475	min. 51		46 – 48	
NiFe47	2.4478	min. 50		47 – 49	
NiFe47Cr [b]	2.4486	min. 47	5.5 – 6.5	47 – 49	
NiFe48Cr	2.4480	min. 50	0.7 – 1.0	47 – 49	
Ni49Cr	1.3921	min. 48	0.7 – 1.0	49 – 51	
Ni29Co18 [c]	1.3981	min. 28		53 – 55	17 – 18 Co
Ceramic-to-metal seals					
Ni42	1.3917	min. 41		56 – 58	
Ni28Co23	1.3982	min. 27		47 – 49	22 – 24 Co

[a] Materials with numbers in group 1 are iron-base alloys.
[b] Especially for soft lead glasses.
[c] Especially for borosilicate glasses.

The pure Ni – Fe alloys do not rust in air and have limited corrosion resistance. Their notched bar impact toughness values, fracture elongations, and reduction in area are high, even at low temperatures. The physical properties of the binary Ni – Fe alloys are given in [12].

Alloys with Controlled Thermal Expansion and for Glass-to-Metal Seals. Alloys having a nickel content of 35 – 55 % Ni have low coefficients of thermal expansion within the temperature range 0 – 100 °C (Fig. 3). For nickel contents above 55 % the expansion coefficients at 0 °C are higher than that of the alloy with 36 % Ni; however, they increase less rapidly with increasing temperature (Fig. 3). Typical applications of these alloys include tape measures and precision equipment, thermostats, temperature regulators, and bimetallic strips.

Whereas addition of other metals usually increases the thermal expansion coefficient of iron – nickel alloys, at room temperature the addition of cobalt lowers it. The cobalt/nickel ratio must be fixed so that the transition temperature Ar_3 is not above −86 °C and the material is completely in the γ-area. Most commercial Ni – Fe – Co alloys contain 27 – 35 % Ni and 16 – 28 % Co, the remainder being Fe. Their main application is for making glass-to-metal seals. Seals for types of glass with higher expansion coefficients are made of Ni – Fe – Cr alloys.

Figure 3. Isotherms of the coefficient of thermal expansion of annealed nickel – iron alloys [12]

Alloys with Controlled Modulus of Elasticity. The Young's modulus of Ni – Fe alloys increases with nickel content (Fig. 4). The moduli of elasticity of magnetically saturated and cold-

strengthened materials are higher than those of demagnetized or annealed materials [12]. The Ni – Fe alloys with temperature-dependent Young's moduli are used mainly for springs, diaphragms, and instrument components.

Figure 4. Modules of elasticity of nickel – iron alloys [12]

Soft Magnetic Nickel – Iron Alloys (see also → Magnetic Materials). Alloys containing 72 – 83 % Ni are crystalline materials with the best soft magnetic properties. Higher permeability values can be obtained by heat treatment. These alloys are used for magnetic shielding, medium-frequency transformers, chokes, and relays.

Alloys containing 45 – 68 % Ni have high saturation induction properties and are used for electrical measurement and leakage current protection in the 300 – 500 mA range. These alloys have a round hysteresis loop. A suitable combination of alloying and heat treatment can produce Ni – Fe alloys with rectangular or flat hysteresis loops. The latter also have very low remanence and small coercive field strengths.

Other soft magnetic materials are the amorphous alloys based on Ni, Fe, and Co, which contain additional alloying elements – boron and silicon – in amounts of 5 – 15 %. These inhibit crystallization. These alloys are called metallic glasses (→ Metallic Glasses) and are usually made as thin strips by extremely rapid cooling of a melt on a rotating metal roller. A typical amorphous alloy (Vibrovac 4040) with 40 % Ni, 40 % Fe, the remainder metalloids, has the following typical properties:

Saturation induction	T = 0.8
Saturation magnetostriction	8×10^{-6}
Static coercive field strength	10 mA/cm
Specific electrical resistance	$1.35\ \Omega \cdot mm^2/m$
Tensile strength	1500 – 2000 MPa

Fabrication of Nickel – Iron Alloys. The fully austenitic Ni – Fe alloys can be cold or hot worked. Cold hardening can be eliminated or reduced by annealing at 800 – 870 °C. Owing to the sensitivity of nickel towards sulfur (formation of a nickel – nickel sulfide eutectic), a sulfur-free annealing atmosphere is necessary. For etching of metallographic samples, a mixture of 10 % nitric acid and 10 % hydrochloric acid at ca. 70 °C is used. For machining of Ni – Fe alloys machining data and tool design used for austenitic Cr – Ni steels can be approximately applied [10–12].

4. Nickel – Copper Alloys

The binary phase diagram for nickel and copper shows mixed crystals for all ratios of nickel to copper (Fig. 5). There are therefore many technically used Ni – Cu alloys, the most important being those covered by DIN 17 743 (Table 5). The strength values for the various semi-finished products are given in DIN 17 750 – 17 753 and ASTM B127, B163, B164, B165, and B564.

Figure 5. Binary phase diagram nickel – copper [13]

Table 5. Composition of wrought nickel – copper alloys [14]

Designation	Material number	Chemial composition, wt %									Typical application
		Ni + Co ∗	Al	C	Cu	Fe	Mn	S	Si	Ti	
NiCu30Fe	2.4360	min. 63			28	1.0					corrosion-resistant
		max.	0.5	0.15	34	2.5	2.0	0.02	0.5		components
LC-NiCu30Fe	2.4361	min. 63			28	1.0					corrosion-resistant
		max.	0.5	0.04	34	2.5	2.0	0.02	0.3		components
NiCu30Al	2.4375	min. 63	2.2		27	0.5				0.3	age-hardenable
		max.	3.5	0.2	34	2.0	1.5	0.015	0.5	1.0	alloy for corrosion-resistant components

∗ Max. 1 % Co.

Nickel – copper alloys do not diffuse readily. Rapid cooling from the liquid state produces inhomogeneous single-phase crystals in which the center is rich in nickel. Hot working and annealing produce a homogeneous structure in wrought semi-finished products.

Nickel – copper alloys are very resistant to corrosion by alkaline solutions, nonoxidizing salts, and seawater. The addition of 1 – 2 % Fe improves corrosion resistance. The precipitation-hardenable alloy NiCu30Al is important as a high-strength, corrosion-resistant material for components, such as propeller shafts of ships, that remain in contact with seawater for long periods.

Welding materials for Ni – Cu alloys are specified in DIN 1736, parts 1 and 2 (see also Chapter 7) [13, 14].

5. Nickel – Chromium Alloys

Nickel and chromium form solid solutions over a wide range. Nickel – chromium alloys are characterized by their high corrosion resistance at normal and elevated temperatures (resistance to scaling), good high-temperature strength, and high electrical resistance. There are basically three groups of alloys:

1) Ni – Cr – (Fe) alloys with high electrical resistance for heating elements
2) Ni – Cr alloys (with Fe and other alloying elements) with good corrosion resistance
3) Ni – Cr alloys with high-temperature strength and creep resistance, mostly age-hardenable.

Nickel – Chromium – (Iron) Electrical Resistance Alloys. Nickel-based alloys are used for heating elements and electrical shunts: their compositions are given in Table 6 and their physical properties in [15]. Since these alloys are used as heating elements at temperatures which can exceed 1000 °C and are sometimes required to undergo rapid cooling, they must be resistant to high temperatures and rapid temperature changes as well as to oxidizing, neutral, and reducing atmospheres [15]. The electrical resistance depends on temperature and heat treatment [15].

Corrosion-Resistant Nickel – Chromium – Iron Alloys. These alloys have significantly better corrosion resistance than austenitic Cr – Ni

Table 6. Composition and density of some electrical resistance alloys [18]

steels and continue the alloy series Ni – Cr – Fe to higher nickel contents. The many alloys are resistant to wet corrosion at normal and elevated temperature and to corrosive gases and slags at high temperature, and the most important of them have been given standard specifications in the industrialized countries. An overview is given in Table 7 (see previous page). Alloys for rolling and forging with increased chromium contents up to 30 % have been developed to improve resistance to corrosion and scaling (Table 7). Strength properties are specified in DIN 17 750 – 17 753 and ASTM (Table 1). If good strength properties at high temperatures are required, the age-hardenable Ni – Cr alloys are used [16–20].

Not only are Ni – Cr – Fe alloys more resistant to general corrosion than stainless steels, but they are also resistant to stress corrosion cracking and pitting in many environments.

Nickel – Chromium – Molybdenum Alloys and Nickel – Molybdenum Alloys. If even better resistance to wet corrosion is required, nickel – chromium alloys with molybdenum additions of 3 – 16 % and sometimes other alloying elements (e.g., Cu) are specified. The Ni – Cr – Mo alloys are particularly resistant to oxidizing acids and gases, whereas the Ni – Mo alloy is resistant to reducing acids. Compositions are given in Table 7 [21–24].

Creep-Resistant, Age-Hardenable Nickel Alloys with High-Temperature Strength [25–29]. With the elements Ti, Al, and Nb, nickel forms intermetallic compounds of the type Ni_3Ti (Al, Nb) which on age hardening (e.g., 16 h at 700 °C) precipitate in a finely dispersed state as a γ'-phase within the basic austenitic structure and at the grain boundaries. The resistance to slipping so produced gives good high-temperature strength and creep resistance, defined as creep rupture strength or creep strength for a defined stress and duration (e.g., 10 000 h). Although wrought nickel and all nickel-base alloys may be artificially age-hardened if alloyed with Ti, Al, and Nb, this process is mainly used with Ni – Cr – (Fe) alloys. The degree of creep resistance is determined by the total content of Ti, Al, and Nb. Vacuum melting and control of grain size and structure also contribute to improvement of creep resistance. The strength of the matrix can be improved by alloying with Co, V, and other elements.

From the large number of age-hardenable superalloys, some widely used typical alloys are summarized in Table 8. Creep rupture strength curves are given in Fig. 6 (see next page). More recently developed grades contain preferentially niobium as an ageing element, if fusion weldability is required (e.g., for gas turbine components made of sheet). Age-hardenable alloys with a reduced Ni content of 38 % (e.g., X1NiCrNb 38 13) have low coefficients of thermal expansion (Fig. 7), which enables very close tolerances of turbine components (higher power, reduced fuel consumption).

Although higher Cr contents have a negative influence on the creep strength of superalloys, they significantly improve the corrosion resistance (Fig. 8).

Figure 7. Coefficient of thermal expansion of two creep resistant superalloys [30]

Oxide Dispersion Strengthened and Mechanically Alloyed Superalloys (→ High-Temperature Materials). Nickel alloys with very good high-temperature strengths at operating temperatures above 1100 °C can be produced by powder metallurgical processes. The matrix powder, which usually consists of an atomized precipitation-hardenable alloy powder, e.g., NiCr20Ti, is mixed with a metal oxide powder (e.g., Y_2O_3) in an attritor. The mechanically alloyed powder mixture is then hot hydrostatically pressed into blooms and then forged or hot rolled.

Figure 8. Corrosion resistance against 75 % Na_2SO_4/25 % NaCl at 900 °C

Precipitation hardening by Ni_3Ti and dispersion hardening by metallic oxide are thus combined and establish the superior creep resistance of the alloys over a wide range of temperatures (Fig. 9). The chemical compositions

Inconel MA 6000	bal.	15	4.5	2.5	0.01	0.15	1.1	2.0 Ta, 2.0 Mo, 4.0 W

of such alloys, also known as ODS (oxide dispersion strengthened superalloys), and used in industry as high-temperature construction materials, are given in Table 9. Above 900 °C, creep rupture strengths of ODS alloy MA 6000 are superior to those of the high-temperature superalloy Mar M200 + Hf made by melting and forging.

6. Nickel Casting Alloys

All nickel alloy groups include foundry alloys whose composition is optimized for casting. Most nickel alloys for casting contain 1.5 – 2 % Si, some grades up to 6 % Si, to improve erosion and abrasion resistance (Table 10). Resistance to seizing is also improved by silicide formation by aging (soft annealing, then treatment at 800 °C for 4 – 6 h). With pure nickel (91 – 96 % Ni),

higher carbon contents lead to graphite precipitation and improvement of galling resistance; mechanical and physical properties are given in [37,38]. With Si contents up to 1.6 %, fabrication welding is possible to a limited extent using filler metals of similar type, as standardized in DIN 1736 (see Chap. 7). At higher Si contents these materials are not weldable. The Ni – Cu and Ni – Cr – Fe grades with 1.2 – 2 % Nb have good weldability. Construction welding can be applied as well as joining with components made of wrought alloys.

Castings with good resistance to hot gases and ash from crude oil combustion can be produced with Ni – Cr alloys containing 40 – 60 % Cr. Alloying with ca. 1.5 % Nb gives improved high-temperature strength and elongation. Although these alloys cannot be hot worked owing to their high chromium content, there are filler metals of similar composition produced using a special metallurgical treatment process, so that coated electrodes, wires, and cast rods can be manufactured for fusion welding. Compositions and properties of the NiCr50 alloy with and without Nb addition are given in [42]. The addition of niobium improves the high-temperature strength [43] and high-temperature corrosion resistance of NiCr50.

Figure 10. Oxidation resistance of G-NiCr50 and G-NiCr50Nb (duration of test: 1000 h) [43]

A typical application is for tube support hangers for chemical furnaces and power station boilers fired with heavy crude oil (Table 11 and Figure 10) [37–43].

7. Welding Filler Metals for Nickel Alloys

For solid solution alloys, which are very suitable for welding, the weld material is supplied in the form of bare wires, wire electrodes, and coated electrodes for all fusion welding processes with the exception of gas welding (oxy-acetylene). These materials are standardized in the following standards: Germany: DIN 1736, parts 1 and 2 [46,47]; United States: AWS specifications A 5.11 and A 5.14 [49,50]; United Kingdom: BS 2901, parts 1 and 2.

The strength properties of the weld metals listed in DIN 1736, part 2 exceed those of the solid solution alloys in the annealed base material. The components are normally welded in the soft-annealed condition. During welding, pure nickel and the Ni – Cu alloys are sensitive to all forms of sulfur, which forms a nickel – nickel sulfide eutectic on heating above 400 °C. This penetrates along the grain boundaries and causes hot and cold cracking under tensile stress. To prevent nitrogen pores in the weld metal, the welding materials contain Ti, Al and/or Nb, which combine with nitrogen to form nitrides; they also react with oxygen to form oxides and with carbon monoxide to give carbides.

The Ni – Cr – Fe alloys that contain 30 – 40 % Ni (e.g., X10NiCrAlTi3220 and NiCr21Mo) are rather susceptible to hot cracking (Fig. 11, see next page) and are preferably welded with filler metals of higher nickel content. The Ni – Cr

Figure 11. Hot cracks in the heat affected zone of alloy 800 (X10NiCrAlTi3220)

Figure 12. Effect of cold work on hardness of nickel alloys [60]

welding materials are also specified for joining different base materials (e.g., austenitic to ferritic steels) and for joining low-temperature nickel steels.

Age-hardenable high-temperature alloys have limited weldability or cannot be fusion welded. They are brazed (Chap. 8), resistance welded, or if possible welded by the MIG or WIG processes, with or without a matching filler metal. The number of layers is limited because of partial precipitation hardening from the welding heat. Fusion welded joints in age-hardened alloys have a creep strength that is generally 10 – 15 % lower than that of the base material [44–52].

8. Nickel Brazing Alloys

Nickel brazing alloys are used for high-temperature brazing of nickel, cobalt, and superalloys if these materials are not suitable for welding. The nickel-base brazing alloys are specified in DIN 8513 part 5 and in corresponding the ISO Standard. Owing to their composition, they combine low melting temperature with high-temperature strength.

They are supplied as pastes, powders, strip, and wires. Brazing is usually carried out in vacuum, under argon, or sometimes in a reducing atmosphere.

For vacuum brazing, the carefully cleaned component is positioned in the furnace which is evacuated to 0.1 Pa. The component is then heated to the brazing temperature and, after a short holding time, cooled in the vacuum.

The brazing process is used for bonding engine and gas turbine parts, in nuclear technology, and for fabrication of high-tech components [53–59].

9. Fabrication of Nickel-Base Alloys

Hot Forming. Wrought nickel-base alloys are generally supplied in the soft annealed or solution annealed condition. Hot forming is usually performed by the producers of the alloys or by specialized fabricators of forgings, tube bends, dished ends, etc. Single-phase nickel alloys have to be heated for both annealing and hot forming in sulfur-free furnace atmospheres to temperatures between 1130° and 1180 °C, depending on the type of alloy. Hot forming must be performed between 950 and 1000 °C. Rapid cooling through the 750 to 550 °C temperature range is recommended for Ni – Cr alloys, to avoid carbide precipitation. Soft annealing is advisable after all hot forming operations.

Forging of age-hardenable alloys is more critical because of the narrow temperature range in which hot forming can be performed and due to the high strength of such alloys at the lower limit of the forging temperature range.

Cold Forming. All single-phase alloys with a face-centered cubic structure have excellent cold formability due to the relatively large difference between the yield strength and the ultimate tensile strength. During cold forming, nickel-base alloys work harden more rapidly than unalloyed steel or copper (Fig. 12). Due to

the high modulus of elasticity, similar to that of austenitic stainless steel, (180 – 220 GPa), a certain amount of spring back occurs during cold forming. The strain rate influences the work hardening: fast forming produces a higher proof strength than slow forming. For cold forming operations, heavy duty lubricants have to be applied to avoid tool to metal seizing and wear.

Heat Treatment. Heat treatment may be necessary after cold forming to achieve a fine-grain structure (recrystallisation) and improved ductility. For single-phase alloys, soft annealing is normally sufficient. Precipitation hardening alloys must be solution annealed before aging.

If the higher strength resulting from cold forming is to be maintained, stress relieving can be applied. Heat treatment is performed at the following temperatures:

	stress relieving	soft annealing
Ni99	400 – 500 °C	820 – 920 °C
NiCu30Fe	500 – 650 °C	870 – 980 °C
NiCr15Fe	650 – 750 °C	950 – 1100 °C

Pickling. Pickling procedures differ for nickel alloys according to the following groups:

1) pure nickel and Ni – Cu alloys
2) Ni – Fe alloys
3) Ni – Cr and Ni – Cr – Mo alloys.

The pickling treatment depends also on the surface condition of the metal. Producers of nickel alloy semifinished products apply descaling by shot blasting and pickling in a solution containing 20 – 25 % nitric acid and 3 – 5 % hydrofluoric acid at ca. 40 °C. For fabricators the removal of tarnish and oxides from the surface is dominant: a solution of water, sulfuric acid, and salt (NaCl) can be applied at 20 – 40 °C for a few seconds. For Ni – Cu alloys, tarnish can be removed with an aqueous solution of nitric acid and salt at 20 – 40 °C within a few seconds. The Ni – Cr – (Fe) alloys require more sophisticated procedures; use of fused salts for pretreatment is recommended. For continuous operations, electrolytic baths are also applied. Special formulas have been developed for removal of lead and zinc (residues from tools), iron inclusions in the surface, and machining fluids, which can cause discoloration. Details on suitable pickling solution formulations can be obtained from producers of the alloys [59, 60].

1. Introduction

Of the worldwide production of nickel, only about 3% is in the form of compounds if ferronickel, nickel oxide, and partially reduced nickel oxides used in the metallurgical industry are excluded.

The main uses of nickel compounds fall into four areas:

1) *Electroplating*. This includes electroforming and electroless nickel plating as well as conventional nickel electroplating.
2) *Catalysis*. Nickel, its alloys and compounds serve as catalysts for numerous chemical reactions. The main uses of nickel catalysts, prepared from nickel compounds, are in steam reforming, hydrocracking, and in hydrogenation reactions, including methanation.
3) *Batteries*. There are various routes to the nickel hydroxide used as the active mass in nickel – cadmium batteries.
4) *Pigments*. These include colorants in enamels, glassware, ceramics, and plastics.

Like all transition metals, nickel forms numerous complexes. These are of academic rather than industrial importance. Most nickel compounds are green; some are blue.

Much information is available from the standard reference works [1 – 3] and a review [4]. There is an extensive review of the coordination chemistry of nickel in [5].

2. Inorganic Nickel Compounds

Nickel(II) amidosulfate [*13770-89-3*], nickel sulfamate, $Ni(NH_2SO_3)_2 \cdot 4\ H_2O$, M_r 322.94 is a highly soluble salt which is used in solution in the electrolyte for nickel electroforming processes, giving low stress deposits.

Commercially, it is available not as a solid but as a solution containing about 11% nickel. This is usually prepared by dissolving nickel powder in a hot solution of sulfamic acid ($HSO_3 \cdot NH_2$), but soluble nickel oxide, nickel hydroxide, or nickel carbonate can also be used. Short reaction times are necessary because of the hydrolysis of sulfamic acid to sulfuric acid.

Nickel(II) ammonium sulfate [*7785-20-8*], $NiSO_4 \cdot (NH_4)_2SO_4 \cdot 6\ H_2O$, M_r 395.00, can be crystallized as blue-green crystals from a solution containing the two components in the appropriate ratio. It has low solubility in water, ca. 25 g/L at 20°C. The salt was formerly used in electroplating, but now its uses are very limited.

Nickel(II) Carbonate. Although a hydrated carbonate $NiCO_3 \cdot 6\ H_2O$ and the anhydrous form $NiCO_3$ exist, the industrially important compound is the bright-green, rhombic basic nickel carbonate approximating to $2\ NiCO_3 \cdot 3\ Ni(OH)_2 \cdot 4\ H_2O$ [*29863-10-3*], M_r 587.57. It is virtually insoluble in water, but dissolves in acids with evolution of carbon dioxide. Heating

to above ca. 450°C in air gives a reactive nickel oxide with a high specific surface area.

Commercial basic nickel carbonate is made by precipitation from a nickel solution, usually the sulfate, with sodium carbonate. The exact composition depends on the temperature and the concentrations of the components in solution.

Basic nickel carbonate is used for pH adjustment in nickel electroplating baths, in catalyst production, and in the manufacture of some nickel pigments and specialty nickel compounds.

Demand for basic nickel carbonate has recently increased due to the use of zinc – nickel plating of steel by the automotive industry. In one electroplating method, the nickel in solution is replenished by basic nickel carbonate.

It is also possible to prepare nickel carbonate by dissolving nickel in ammonium carbonate solution in the presence of air and carbon dioxide. Boiling off the ammonia and carbon dioxide precipitates basic nickel carbonate. This method forms part of the Caron process for the refining of nickel (→ Nickel). The carbonate is further processed to nickel oxide or nickel metal.

Nickel(II) Halides. Nickel forms dihalides with all four halogens, and each dihalide forms one or more hydrates. Only the chlorides are of industrial importance, particularly the hexahydrate $NiCl_2 \cdot 6\ H_2O$, which is available either as a solid or as a concentrated solution.

Table 1 lists some properties of the dihalides and the hydrate usually encountered. Known hydrates are $NiF_2 \cdot 4\ H_2O$, $NiCl_2 \cdot x\ H_2O$, (x = 2, 4, 6, 7), $NiBr_2 \cdot x\ H_2O$ (x = 2, 3, 6, 9), $NiI_2 \cdot x\ H_2O$ (x = 4, 6).

Nickel dichloride hydrates are stable over the following temperature ranges:

$NiCl_2 \cdot 7\ H_2O$	low temperature
$NiCl_2 \cdot 6\ H_2O$	up to 36.25°C
$NiCl_2 \cdot 4\ H_2O$	36.25 to 75°C
$NiCl_2 \cdot 2\ H_2O$	above 75°C

The difluoride is only slightly soluble in water, but the other halides are very soluble (e.g., 117 g $NiCl_2 \cdot 6\ H_2O$ per 100 mL solution at 20°C).

The difluoride has a tetragonal structure, and the other dihalides have hexagonal layer structures. They are relatively stable, and can be melted or sublimed in a vacuum or under an inert atmosphere.

Production. The anhydrous halides can be made by direct reaction of the elements at high temperature or in nonaqueous solution, although the fluoride is better made indirectly. They are also formed by dehydration of the hydrates in a stream of the hydrogen halide gas to prevent formation of nickel oxide.

The hydrates can be made by dissolving nickel metal, oxide, hydroxide, or carbonate in an aqueous solution of the halogen acid HX, followed by crystallization. Commercially, nickel dichloride hexahydrate is usually produced by dissolving nickel metal in hydrochloric acid, and then crystallizing. Nickel dichloride solutions are important in chloride-based processes for the extraction of nickel, but nickel metal is usually recovered by electrowinning.

Uses. Nickel dichloride hexahydrate is important in electroplating; it is used together with nickel sulfate in the Watts plating bath. Table 2 lists the purity specifications for its use in electroplating. It is also used in the production of some catalysts. Uses of the other dihalides are very minor.

Table 2. Specifications of nickel chloride hexahydrate for electroplating

Nickel(II) hydroxide [*12054-48-7*], $Ni(OH)_2$, M_r 92.71, d 4.15, $\Delta H°$ (25°C) −514 kJ/mol. Treating a nickel salt solution with an alkali-metal hydroxide solution gives a green gelatinous precipitate of nickel hydroxide, also known as nickel hydrate. Filtering, washing, and drying give the pure compound. The precipitation conditions affect the physical characteristics of the nickel hydroxide produced.

Nickel hydroxide is virtually insoluble in water, but it is soluble in dilute acids, giving a nickel salt solution, and in ammoniacal solutions a blue ammine complex is formed. Heating to ca. 250°C drives off water, leaving nickel oxide.

Nickel hydroxide has some use as an intermediate in catalyst production, but its main use is as the active mass in the positive electrode in nickel – cadmium batteries. In pocket-plate electrodes, pellets of nickel hydroxide are used. In sintered electrodes, the nickel hydroxide is prepared within the electrode either by precipitation or electrochemically.

There are various hydrated oxides or hydroxides containing Ni(III) and possibly Ni(IV), some of which are not well characterized. The compounds are black and are referred to as nickel peroxide, nickelic hydroxide, or nickel black.

The β-NiO·OH, obtained by the oxidation of nickel salts in alkaline solution with an oxidizing agent such as sodium hypochlorite, is well characterized. It is also formed in batteries when Ni(II) hydroxide in a nickel electrode is charged.

Persulfate oxidation of nickel(II) hydroxide gives a substance formulated as $NiO_2 \cdot x\ H_2O$.

A commercial "nickel peroxide" corresponded to $Ni_2O_3 \cdot 2\ H_2O$, and gave $Ni_2O_3 \cdot H_2O$ (equivalent to NiO·OH) on partial dehydration [6].

Nickel(II) Nitrate. The commercially available compound is the green hexahydrate [*13478-00-7*], $Ni(NO_3)_2 \cdot 6\ H_2O$, M_r 290.8, d 2.05, $\Delta H°$ (25°C) −2212 kJ/mol. It is very soluble in water. On heating, the hexahydrate dissolves in its own water of crystallization at 56°C. Progressive heating drives off the water of crystallization, giving basic nitrates and finally nickel(II) oxide.

The stability ranges of the hydrates are:

$Ni(NO_3)_2 \cdot 9\ H_2O$	below −3°C
$Ni(NO_3)_2 \cdot 6\ H_2O$	−3 to 54°C
$Ni(NO_3)_2 \cdot 4\ H_2O$	54 to 85.4°C
$Ni(NO_3)_2 \cdot 2\ H_2O$	85.4 to ca. 105°C

Nickel nitrate solution can be produced by dissolving nickel in nitric acid. The reaction is vigorous, and without careful control loss or breakdown of the nitric acid occurs, forming, among others, ammonium nitrate. The dissolution of nickel(II) oxide in nitric acid is easier to control; the hexahydrate is produced by crystallization of the resulting solution.

It is difficult to prepare the pale-green, anhydrous nickel(II) nitrate by dehydration of the hexahydrate. It can be obtained by dehydration with dinitrogen pentoxide in fuming nitric acid, or from nickel tetracarbonyl and dinitrogen tetroxide.

Nickel(II) nitrate hexahydrate is widely used in the production of nickel catalysts, by impregnating an inert carrier and decomposing the nitrate. It is also used in the formation of the nickel(II) hydroxide active mass in sintered nickel electrodes for nickel – cadmium batteries.

Nickel(II) Oxide. Nickel oxide [*1313-99-1*], NiO, M_r 74.69, d 6.8, $\Delta H°$ (25°C) −240 kJ/mol, is green, with a cubic rock-salt structure. It occurs in nature as bunsenite. The exact color depends on factors such as purity and crystallite size. In general, the properties of nickel oxide depend on the method of preparation, especially temperature.

Nickel(II) oxide has a defect structure $Ni_{1-y}O$, which is responsible for its p-type semiconductor properties. In addition, nickel oxide can absorb surface oxygen to give higher O : Ni ratios. There is little evidence for Ni_2O_3

as a bulk compound, although it may exist as a surface compound on NiO.

World production of "nickel oxide" is ca. 40 000 t/a from INCO in Canada, Greenvale in Australia, and from Cuba, but only about 4000 t of this is chemical nickel oxide. The majority is metallurgical nickel oxide, or partially reduced nickel oxide containing 85 – 90% nickel, used mainly in the stainless steel industry. Chemical nickel oxide is available in two forms: green or black.

Production. Green nickel oxide can be made by calcining almost any nickel compound in air, for example, the nitrate, oxalate or hydroxide, at ca. 1000°C. It can also be made by oxidation of carbonyl nickel powder, but some care is needed to ensure complete oxidation.

Black, or soluble, nickel oxide is made by calcining basic nickel carbonate at ca. 550°C; it contains a slight excess of oxygen.

The green oxide is rather refractory, and dissolves only slowly in mineral acids. The black oxide is more reactive and dissolves readily. Both forms are insoluble in water and are easily reduced, for example by hydrogen, to nickel metal.

Uses. Nickel oxide is used in the production of catalysts, in the enamel industry for making frit, in the glass and ceramics industries, and in the manufacture of ferrites for the electronics industry.

Black nickel oxide is particularly suitable for dissolving in acids as a first step in the production of specialty nickel salts.

Higher oxides such as Ni_2O_3, and NiO_2 have been proposed but there is little evidence for their existence free of water.

Nickel(II) Sulfate. Two forms of nickel(II) sulfate are commercially available. The most common is the blue-green, tetragonal hexahydrate [*10101-97-0*], α-$NiSO_4 \cdot 6\ H_2O$, M_r 262.84, d 2.07, ΔH° (25°C) −2683 kJ/mol, nickel content 22.3%, which crystallizes from solution between 30.7 and 53.8°C. The other form is the green, orthorhombic heptahydrate [*10101-98-1*] $NiSO_4 \cdot 7\ H_2O$, M_r 280.85, d 1.95, nickel content 20.9%, which crystallizes from solution below 30.7°C. Crystallization above 53.8°C gives green β-$NiSO_4 \cdot 6\ H_2O$.

The hydrates are readily soluble in water. The solubilities in grams per liter of solution are (the temperature in °C is given in parentheses):

$NiSO_4 \cdot 7\ H_2O$	578	(10)
$NiSO_4 \cdot 7\ H_2O$	775	(30)
α-$NiSO_4 \cdot 6\ H_2O$	770	(40)
α-$NiSO_4 \cdot 6\ H_2O$	851	(50)
β-$NiSO_4 \cdot 6\ H_2O$	959	(60)
β-$NiSO_4 \cdot 6\ H_2O$	1258	(100)

Data also exist for the solubility of nickel sulfate in sulfuric acid [7].

Heating the hydrates causes dehydration. Hydrates with 4 or 1 molecule of water are stable. The bright yellow, cubic, anhydrous salt $NiSO_4$ [*7786-81-4*], M_r 154.75, d 3.68, ΔH° (25°C) −873 kJ/mol, is obtained above 330°C. This decomposes above ca. 800°C to give nickel oxide and sulfur trioxide. The lower hydrates can also be obtained by crystallization from nickel sulfate solutions containing excess sulfuric acid. They dissolve only slowly in water. Basic sulfates also exist.

Production. The worldwide production capacity is about 40 000 t/a, from producers in Europe, Japan, China, and the former Soviet Union. Most of the nickel sulfate is a byproduct of electrolytic copper refining. A bleed stream is purified, finally giving a solution from which nickel sulfate is crystallized.

Table 3. Specifications of nickel sulfate hexa- or heptahydrate for electroplating

	BS 564 (1970) (6 or 7 hydrate), %	DIN 50970 (6 hydrate), %
Ni + Co	20.7 min.	22.0 min.
Co	1% of total metal, max.	0.5 max.
Cu	0.002 max.	0.002 max.
Fe	0.005 max.	0.005 max.
Pb	0.002 max.	0.002 max.
Zn	0.002 max.	0.006 max.
Cd		0.005 max.
As		0.001 max.
Insolubles	0.05 max.	0.05 max.
pH (40% w/v)	2 min.	

Nickel sulfate is also produced by dissolving nickel or nickel oxide in sulfuric acid and

crystallizing. Several nickel refineries produce nickel sulfate solution by leaching nickel mattes with sulfuric acid, but the nickel is usually recovered as nickel metal by electrowinning.

Uses. The main use of nickel sulfate is as the electrolyte in nickel electroplating baths. Table 3 lists the standards covering nickel sulfate for use in electroplating. It is also used in electroless nickel plating, in catalyst manufacture, and in the production of other nickel compounds.

Nickel Sulfides. Nickel(II) sulfide [*1314-04-1*], NiS, M_r 90.75, *d* 5.65, $\Delta H°$ (25°C) −82 kJ/mol, *mp* 797°C.

Neutral nickel(II) salt solutions react with ammonium sulfide initially to give black α-NiS, a hydrous, amorphous precipitate of the type Ni $(SH,OH)_2$. At low pH, this crystallizes to give rhombohedral γ-NiS, whereas in more alkaline solution hexagonal β-NiS is formed.

The γ-form occurs in nature as millerite. This shows little deviation from stoichiometry, but a high-temperature form has a stoichiometry range.

Other nickel sulfides exist, some of which occur in nature. These are Ni_3S_2, Ni_7S_6, Ni_3S_4, and NiS_2. All can be prepared by fusing the correct proportions of the elements.

Sulfide minerals are a major source of nickel, and nickel sulfide is an important intermediate in refining processes. The main use of nickel sulfides is as catalysts, for example, in the hydrogenation of sulfur compounds. The catalyst can be prepared in situ by sulfiding a supported nickel catalyst.

Nickel(II) tetrafluoroborate [*14708-14-6*], $Ni(BF_4)_2 \cdot 6\,H_2O$, M_r 340.41 can be made as apple green needles by reacting fluoroboric acid with basic nickel carbonate, and crystallizing from solution. It has limited use in specialty high-speed nickel plating process, and other minor uses.

Nickel Complexes. In common with all transition metals nickel forms a vast number of inorganic complexes with different oxidation states and geometries. Only the ammine complexes, which are important in ammonia-based leaching processes, have industrial significance.

The structural, spectral, and magnetic properties of nickel complexes are important in studies of transition-metal complex chemistry. In particular, there are concentration and temperature dependent anomalies in properties due to polymerization and equilibria between different geometries.

The most common complex ion is octahedral Ni(II), for example, the green $Ni(H_2O)_6^{2+}$ in aqueous solution. The electronic structure of these complexes is [Ar]$3d^8$ with two unpaired electrons, and hence they are paramagnetic. Other species can displace water molecules, for example, ammonia molecules in ammine complexes $[Ni(H_2O)_x(NH_3)_{6-x}]^{2+}$, $x = 0 - 6$, which are blue or purple. The complex ion $[Ni(H_2O)_4\,(NH_3)_2]^{2+}$ is the required ion in solution for the production of nickel powder by pressure reduction of solutions by hydrogen.

Four-coordinate Ni(II) complexes are quite common, either diamagnetic square planer complexes such as the yellow $Ni(CN)_4^{2-}$ or paramagnetic tetrahedral complexes such as $NiCl_4^{2-}$. Five-coordinate Ni(II) complexes also exist, and are either trigonal bipyramidal or square pyramidal.

Complexes of nickel in lower oxidation states are mostly based on carbonyl ligands. An example of Ni(0) is $Ni(PF_3)_4$ and of Ni(I), $Ni(PPh_3)_3X$ (X = Cl, Br, I).

Higher oxidation states are stabilized by electronegative elements, e.g., Ni(III) in the violet K_3NiF_6 and Ni(IV) in red K_2NiF_6, both of which are octahedral.

3. Nickel Tetracarbonyl

Nickel tetracarbonyl [*13463-39-3*], $Ni(CO)_4$, M_r 170.75, *bp* 42.2°C, *mp* −19.3°C, *d* 1.31, is a very toxic colorless liquid. It possesses a significant vapor pressure at ambient temperature (44 kPa at 20°C; 65 kPa at 30°C).

Nickel tetracarbonyl is virtually insoluble in water, but soluble in many organic solvents. It does not react with dilute mineral acids. It is thermally unstable, decomposing to nickel and carbon monoxide. It burns in air with a luminous flame, giving nickel oxide and carbon dioxide, and forms explosive mixtures with air (3 – 34 vol% $Ni(CO)_4$). The molecule is tetrahedral, with linear Ni−C−O bonds. The bonding consists of both a Ni−C σ-bond and π bonding.

Production. Nickel tetracarbonyl is formed by direct reaction of carbon monoxide and finely divided nickel at relatively low temperatures [8]:

$$Ni_{(g)} + 4\,CO_{(g)} \rightarrow Ni(CO)_{4(g)}$$

$$\Delta G = -160410 + 418.27\,T\ \mathrm{J/mol}$$

At atmospheric pressure, the maximum rate of formation of nickel tetracarbonyl is at 130°C for pure nickel. The temperature at which the rate of formation is a maximum decreases in the presence of a catalyst such as sulfur, and increases with pressure. The reverse reaction begins above ca. 180°C. This reversible reaction is the basis of the atmospheric-pressure Mond process and the INCO pressure process for the production of high-purity nickel pellet and powder (→ Nickel, Chap. 6.3). Nickel tetracarbonyl can also be prepared in solution by a variety of methods [9]. Users of nickel tetracarbonyl frequently produce their own supply, but it is commercially available in the United States.

The conditions under which nickel tetracarbonyl is formed are important because of the possibility of corrosion or transfer of nickel within a system, and in view of its high toxicity. The mere coexistence of carbon monoxide and nickel in some form does not mean that nickel tetracarbonyl will form. Other criteria must be met: (1) a fully reduced nickel-containing surface, (2) a reducing gas containing carbon monoxide, (3) the formation must be thermodynamically possible, which generally means low temperature (ambient to 150°C) and high carbon monoxide partial pressures. In addition, the presence of a catalyst such as sulfur accelerates nickel tetracarbonyl formation.

One situation where a significant amount of nickel tetracarbonyl can form is from a finely divided reduced nickel catalyst and carbon monoxide at low temperature. This is well known to users of nickel catalysts, and such conditions are avoided. Other than this, it is rare that significant amounts of nickel tetracarbonyl are formed. Environmentally, precautions preventing contamination of the workplace by the carbon monoxide will also prevent contamination by any nickel tetracarbonyl.

The presence of nickel tetracarbonyl has been suggested but not demonstrated in cigarette smoke and in gases from the combustion of fossil fuels containing nickel. Attempts to detect it in welding fume failed [10].

Uses. Apart from being an intermediate in the carbonyl refining of nickel, nickel tetracarbonyl can be thermally decomposed to nickel plate other materials, for example, in mold production or in a fluidized bed. It is also used as a carbonylating agent or catalyst in organic chemistry.

Analysis. Nickel tetracarbonyl can be analyzed by decomposition and conventional analysis of the nickel, by gas chromatography, UV or IR spectroscopy. There is a highly sensitive method based on the chemiluminescent reaction of nickel tetracarbonyl with ozone [11]. Commercial instruments based on infrared or chemiluminescent analysis are available.

Reactions of Nickel Tetracarbonyl. Nickel tetracarbonyl undergoes oxidation, reduction, and substitution reactions [12, 13]. These are normally carried out in organic solvents below ca. 50°C to prevent thermal decomposition of the nickel tetracarbonyl.

Reaction with various oxidizing agents gives Ni(II) compounds. Concentrated nitric acid gives nickel nitrate. Solutions of nickel tetracarbonyl in organic solvents are oxidized by air to basic nickel carbonate and by halogens to the corresponding nickel dihalide. Decomposition of nickel tetracarbonyl with bromine water is useful as a means of disposal or for analysis.

Reduction reactions, generally with alkali metals, give polynuclear anions formulated as $[Ni_2(CO)_6]^{2-}$, $[Ni_3(CO)_8]^{2-}$, $[Ni_4(CO)_9]^{2-}$, $[Ni_5(CO)_9]^{2-}$, and $[Ni_6(CO)_{12}]^{2-}$. Reduction of nickel tetracarbonyl by alkali metals in liquid ammonia gives a carbonyl hydride $[NiH(CO)_3]_2$, isolated as a tetra-ammoniate.

Interest in substitution compounds of nickel tetracarbonyl blossomed following the publication in 1948 of work by Reppe and coworkers showing that an effective class of catalysts for the trimerization of acetylene compounds could be formed by substituting CO groups in $Ni(CO)_4$ by donor ligands such as triphenylphosphine.

Thousands of substitution compounds of nickel tetracarbonyl have now been prepared. Most are with ligands containing the group 15 elements phosphorus, arsenic, or antimony as

electron donor, but carbon, nitrogen, and unsaturated organic molecules can also serve as ligands.

Some of the simpler substitution compounds with phosphorus ligands are $Ni(CO)_n(PX_3)_{4-n}$, $n = 0 - 3$, X = H, F, Cl, CH_3, C_2H_5, C_6H_5 (substituted phosphines) and X = OCH_3, OC_2H_5, OC_6H_5 (phosphites). The degree of substitution is controlled by steric and electronic effects. For example, with PF_3 and $P(C_6H_5)_3$, only mono- and disubstituted compounds are formed, whereas with PCl_3 and $P(OC_6H_5)_3$ the carbon monoxide molecules can be completely replaced. The tetrakis(ligand) compounds $Ni(PF_3)_4$ and $Ni[P(C_6H_5)_3]_4$ can be prepared by other means. Substitution by chelating ligands is also possible, e.g., $(CO)_2NiL'$ and NiL'_2, where $L' = o\text{-}C_6H_4\text{-}[P(C_2H_5)_2]_2$.

Fewer substitution compounds based on arsenic and antimony have been prepared. Examples include $Ni(CO)_3AsX_3$ (X = CH_3, C_2H_5, C_6H_5, OCH_3, OC_2H_5, OC_6H_5) and $Ni(CO)_3SbX_3$ (X = Cl, C_2H_5, C_6H_5, OC_6H_5).

4. Nickel Salts of Organic Acids

Nickel(II) acetate tetrahydrate [*6018-89-9*], $Ni(CH_3COO)_2 \cdot 4\,H_2O$, M_r 248.86, *d* 1.744, can be obtained as green crystals when solutions of nickel(II) hydroxide or carbonate in acetic acid are evaporated at room temperature. It is readily soluble in water but is insoluble in ethanol.

Anhydrous nickel(II) acetate $Ni(CH_3COO)_2$, *d* 1.798, can be prepared by dehydration of the tetrahydrate in vacuum or by heating the tetrahydrate under reflux with acetic anhydride. When heated in the absence of air these acetates decompose to give a residue of nickel and Ni_3C, evolving, among other products, carbon monoxide and carbon dioxide. Nickel acetate is a suspect carcinogen: the LD_{50} (rat) is 350 mg/kg [14].

Nickel(II) acetylacetonate [*3264-82-2*], $Ni(CH_3COCHCOCH_3)_2$, M_r 256.91, *mp* 230°C (dec.), is obtained as emerald green crystals by dehydration of the dihydrate at 50°C in vacuum; it has an unusual trimeric structure in the solid state [15]. The dihydrate $Ni(CH_3COCH_3)_2 \cdot 2\,H_2O$ is prepared by the addition of acetylacetone to solutions of nickel(II) salts in the presence of a weak base such as sodium acetate. Nickel(II) acetylacetonate is soluble in organic solvents and finds use in the synthesis of organometallic compounds such as nickelocene and bis(cyclooctadiene) nickel. It is also industrially important as a catalyst component in the oligomerization of alkenes and in the conversion of acetylene to cyclooctatetraene [16, 17].

Nickel(II) dimethylglyoximate [*13478-93-8*] bis(dimethylglyoximato) nickel(II), $Ni(C_4H_7N_2\,O_2)_2$, M_r 288.94, is obtained quantitatively as a bright-red precipitate when an alcoholic solution of dimethylglyoxime is added to a neutral or slightly alkaline solution of a nickel(II) salt. This reaction is used in the gravimetric estimation of nickel [18] and is also useful as a spot test for the presence of nickel ions. The structure of this diamagnetic solid [18] shows the nickel(II) ion to be in a square-planar environment; the dotted lines represent strong intramolecular hydrogen bonds.

Nickel(II) formate dihydrate [*15694-70-9*], $Ni(HCOO)_2 \cdot 2\,H_2O$, M_r 184.76, *d* 2.154, is obtained as green crystals by evaporation of a solution of nickel carbonate in formic acid. The anhydrous salt is obtained when the dihydrate is heated to 140°C; at 250°C, finely divided nickel metal is produced. Hence, nickel(II) formate is used in the production of nickel catalysts.

Nickel(II) oxalate dihydrate [*6018-94-6*], $Ni(COO)_2 \cdot 2\,H_2O$, M_r 182.76, precipitates as a green powder when oxalic acid or alkali-metal oxalate solutions are added to nickel(II) salt solutions. When heated in vacuum, it evolves water at 150°C and decomposes completely at 300°C, giving finely divided nickel suitable for use in catalysis or in the production of nickel carbonyl.

5. Organonickel Compounds

Nickel Alkyls and Aryls. Simple σ-bonded alkyls and aryls of nickel are too unstable to exist in the absence of stabilizing ligands. Alkyls can be stabilized, however, by π-bonded aromatic systems, by phosphite ligands, and by bipyridyl. Thus the dimethylnickel bipyridyl adduct exists as green crystals that can be recrystallized from boiling benzene.

Stable aryls can be prepared by reaction of aryl Grignard reagents ArMgX with the bis(phosphine) nickel(II) halide complexes $NiX_2(PR_3)_2$. The yellow or brown products of the types $ArNiX(PR_3)_2$ and $Ar_2Ni(PR_3)_2$ are particularly stable if the aryl group is ortho-substituted (e.g., Ar = *o*-tolyl or mesityl), and such compounds are air stable and can be heated to 80°C without decomposition. Many such compounds have been prepared [19].

π-Bonded Complexes. There is a very extensive chemistry of nickel π-bonded to unsaturated organic molecules. The most important classes of compounds are the η^2-alkene complexes, the η^3-allyls, and the η^5-cyclopentadienyl complexes. Alkene complexes of nickel are of two basic types, both of which contain nickel in zero oxidation state. There are the trigonal, 16-electron complexes and the less common tetrahedral 18-electron complexes. The two most important alkene complexes are described below together with the parent allyl and cyclopentadienyl complexes; these are the starting materials for the preparation of many other organometallic complexes [20].

(Cyclododeca-1,5,9-triene)nickel [*39330-67-1*], $NiC_{12}H_{18}$, M_r 220.96, is prepared by the reduction of nickel(II) acetylacetonate with diethyl-aluminum ethoxide in the presence of cyclododeca-1,5,9-triene (CDT). It forms red, air-sensitive crystals, which can be sublimed in vacuum and are soluble in most organic solvents. The complex normally isolated has all-*trans*-CDT with the nickel atom surrounded trigonally and in a propeller-like fashion by the double bonds.

The two important reactions shown by Ni (CDT) are ligand addition, for example:

$$Ni\,(CDT) + PMe_3 \rightarrow Ni\,(CDT)\,(PMe_3)$$

and ligand substitution reactions by which other tris(alkene)nickel complexes are prepared, for example:

$$Ni\,(CDT) + 3\,CH_2 = CH_2 \rightarrow Ni(CH_2 = CH_2)_3 + CDT$$

Bis(cycloocta-1,5-diene)nickel [*33221-58-8*], $Ni(C_8H_{12})_2$, M_r 275.05, is prepared by reduction of nickel(II) acetylacetonate with triethylaluminum in the presence of cycloocta-1,5-diene (COD):

$$Ni(acac)_2 + 2\,COD + 2\,AlEt_3 \rightarrow$$
$$Ni(COD)_2 + 2\,Al\,(acac)\,Et_2 + C_2H_4 + C_2H_6$$

It can also be obtained by electrolytic reduction of nickel salts in pyridine in the presence of COD, by reduction of nickelocene with lithium in the presence of COD, and by cocondensation of nickel vapor and COD. It crystallizes as orange-yellow crystals from aromatic solvents and can be handled for a short time in air without appreciable decomposition. The structure of $Ni(COD)_2$ has nickel atoms tetrahedrally surrounded by four alkenic double bonds.

In its reactions with ligands, substitution of either one or, more frequently, two COD molecules occurs, and reaction with excess ligand is a widely used method for preparing tetrakis(ligand) complexes for example:

$$Ni(COD)_2 + 4\,PH_3 \rightarrow Ni(PH_3)_4 + 2\,COD$$

Bis(cycloocta-1,5-diene)nickel has found extensive use not only as a starting point for the preparation of many organonickel complexes but also as a catalyst or cocatalyst in a variety of organic reactions such as the polymerization and cyclotrimerization of butadiene, the oligomerization of other alkenes, the isomerization of strained cycloalkanes, and the polymerization of ethene [16]. The polymerization of ethene with a $Ni(COD)_2$ catalyst in the presence of acids such as thiolactic acid occurs at 65°C and 4 MPa and does not require an aluminum component in the catalyst [21].

Bis(η^3-allyl)nickel [*12077-85-9*], Ni $(C_3H_5)_2$, M_r 140.83, is prepared by reaction of allylmagnesium bromide with nickel(II) bromide in ether at −10°C.

It is soluble in ether and crystallizes below 1°C, forming yellow needles. Ethereal solutions are unaffected by deoxygenated water but the solid is pyrophoric in air. It is the simplest example of a whole range of nickel η^3-allyls. The sandwich structure has been established by X-ray analysis on the more stable bis(η^3-methyl allyl)nickel complex [22].

Bis(η^3-allyl)nickel is a very active catalyst for the room temperature cyclotrimerization of butadiene to cyclododeca-1,5,9-triene:

η^3-Allyls of nickel find many uses in catalysis, especially in the oligomerization and isomerization of alkenes [2].

Bis(η^5-cyclopentadienyl)nickel(II) [*1271-28-9*], nickelocene, $Ni(C_5H_5)_2$, M_r 188.88, *d* 1.47, forms dark emerald-green crystals that can be sublimed in vacuum above 80°C and melt in a nitrogen atmosphere with some decomposition at 173 – 174°C. The crystals are only mildly air sensitive, but solutions in organic solvents must be handled under an inert atmosphere. Nickelocene is neither attacked by water nor dissolves in it. The solid is paramagnetic (μ_{eff} = 2.86 BM) and has the sandwich structure as in ferrocene with the nickel atom between planar cyclopentadienide rings.

The simplest laboratory preparation of nickelocene involves the addition of a solution of hydrated nickel(II) chloride in dimethylsulfoxide to a solution of potassium hydroxide and cyclopentadiene in 1,2-dimethoxyethane:

$$NiCl_2 \cdot 6\,H_2O + 2\,C_5H_6 + 2\,KOH \rightarrow Ni(C_5H_5)_2 + 2\,KCl + 8\,H_2O$$

Many other methods are available, however, starting from anhydrous nickel salts with Grignard reagents (or alkali-metal cyclopentadienides) or from nickel metal and cyclopentadiene [23].

Upon oxidation, the orange-yellow nickelocinium ion $(\eta^5\text{-}C_5H_5)_2Ni^+$ is produced; it can be isolated as the tetraphenylborate. The reactions of nickelocene with donor molecules provide a major route to NiL_4 molecules by displacement of both rings. In some reactions only one cyclopentadiene ring is displaced as in, for example, the reaction with nitrogen monoxide, in which the relatively inert $(\eta^5\text{-}C_5H_5)NiNO$ is produced.

Nickelocene has been shown to be an effective catalyst for the oligomerization of alkenes [24], for the isomerization of alkenes [25], for the polymerization of butadiene [26], for the hydrosilylation of alkenes [27], and for the telomerization of butadiene [27].

Nickelocene is carcinogenic with an LD_{50} (rat) of 490 mg/kg [14].

6. Analysis

The classical analytical method for nickel in solution is gravimetric, by precipitation of the red complex with butanedione dioxime (dimethylglyoxime). Other methods include electrodeposition, EDTA titration, and the standard spectroscopic methods of atomic absorption, flame emission, inductively coupled plasma optical emission, and X-ray fluorescence. There is a standard analytical method for nickel in biological tissue [28].

7. Economic Aspects

In general, nickel compounds cost the London Metal Exchange (LME) price for the contained nickel, plus a premium based on the production cost. However, companies producing

nickel compounds, particularly nickel sulfate, as a byproduct of other processes are more flexible in their pricing.

The LME three-month nickel price decreased during the first part of the 1980s from about $ 3 per pound in 1980 to below $ 2 per pound in 1986. The price then rose to over $ 5.50 per pound in 1988, but has since decreased.

8. Toxicology

8.1. Distribution in the Environment

Air. The nickel content of ambient air in general is very low and ranges from below 1 ng/m^3 in the Antarctic [29] up to 5 ng/m^3 in urban air [30]. Higher concentrations are found near fuel incineration sites and in nickel producing or processing industries.

Soil. The topsoil in woodlands contains between 4 and 40 mg Ni/kg dry matter (d.m.) in sandy and clay soils, respectively [30]. The nickel content of agricultural soils varies greatly depending on the mineral matrix and the type of fertilizer administered. Nickel concentrations in German agricultural soils varied between 4 and 400 mg/kg d.m. Use of sewage sludge, which in Germany on average contains 23 mg Ni/kg d.m., further enhances the amount of nickel in soils. Nickel in soils is mainly complexed to inorganic (clay) and organic (humic matter) material and is only soluble in acid environment.

Water. Nickel is mobilized into surface waters mainly by weathering of rocks. River waters in Germany contain nickel predominantly bound to particulate matter (47 – 63 mg/kg) and to a lesser extent in the filterable fraction (15 – 20 µg/L) [30]. The total nickel concentration in coastal waters of the North Sea was found to be 1 – 11 µg/L and that of the Atlantic Ocean only 0.1 – 0.5 µg/L [29]. Sediments may accumulate higher concentrations, for example, sludge in the port of Hamburg contains 50 – 100 mg/kg d.m.

Foodstuffs. The nickel concentration in *drinking water* usually is very low. In Germany, drinking water concentrations are below 5 µg Ni/L [31]. Drinking water supplies on the average 20 µg Ni/d to human nickel intake, of which only 2% is resorbed (see below).

Meat from game and pasture animals contains only traces of nickel close to the detection limit. Beef contained only 1 – 13 µg/kg d.m. with the exception of meat from cattle grazing close to nickel processing facilities [31].

The major sources of nickel supply to humans are *vegetables*, which usually contain 0.05 – 0.34 mg/kg d.m. Higher nickel concentrations are found in cocoa (8 – 12 mg/kg), hazel nuts (0.7 – 2.3 mg/kg), oats (0.3 – 4.8 mg/kg), and soy products (1.1 – 7.8 mg/kg) [32]. In industrialized countries, additional nickel (about 10 mg/d) is taken up from meals cooked in stainless steel pans, which release varying amounts depending on the acidity of the food [33]. The total supply of nickel by nutrition in Germany with mixed diet was estimated to be 90 – 97 µg/d, and with vegetarian diet 185 – 196 µg/day [34].

8.2. Mammalian Toxicology

Nickel has been shown to be an essential trace element in the nutrition of various animal species [35], but in humans no nickel-deficiency symptoms are known. Toxic effects of major concern are sensitization of the skin (contact dermatitis) and carcinogenicity of inhaled nickel compounds.

Resorption, Distribution, and Elimination. The main path of nickel uptake in the general population is by nutrition. Low in quantity but critical for induction of allergic dermatitis is uptake by skin contact with nickel-plated objects. In the nickel producing and processing industry workers are exposed predominantly to breathable nickel aerosols and dusts. Extraordinarily high uptake of nickel through biomembranes occurs by exposition to nickel tetracarbonyl because of its lipophilicity [36].

Oral Resorption. From the estimated average daily human intake of 150 – 250 µg with nutrition, only 1 – 2% is resorbed in the intestine [36].

Inhalative Resorption. Inhalation of nickel compounds in occupational exposures results in nickel accumulation in the lung by about 50-fold for soluble and by up to 500-fold for oxides and

sulfides of low solubility [37]. Even sparingly soluble nickel compounds are bioavailable after deposition in the lung. Inhalation of all types of nickel metal and compounds has resulted in increased concentrations of nickel in blood and urine. It is estimated that a concentration of 90 µg Ni/m^3 results in a concentration of 5 µg Ni/L in blood and about 15 µg Ni/L in urine [38].

Skin Resorption. Cutaneous resorption of soluble inorganic nickel compounds is slow, with the exception of the lipophilic nickel tetracarbonyl, which is easily resorbed and exerts high acute toxicity after penetration through the skin [36].

Distribution. The average nickel content of the human body is about 7 µg Ni/kg body mass. The average concentrations in human body fluids are 0.2 – 0.3 µg Ni/L in serum, 0.34 – 2.3 µg Ni/L in whole blood, about 2 – 3 µg Ni/L in urine, and about 14 mg Ni/kg d.m in feces [36]. In autopsies, human organs contained between 20 and 180 µg Ni/kg d.m. with the highest concentrations in the lung and thyroid and adrenal glands [39].

Elimination. Excretion after oral uptake of soluble nickel salts occurred with a half-life of 10 – 20 h [40]. After accidental oral intake of high doses of soluble nickel a half-life of 60 h was observed [29], and after occupational inhalation by stainless steel welders a half-life of 53 h was estimated [42]. Following inhalative exposure of rats to sparingly soluble nickel compounds, a mean half-life of 90 d was observed [39].

Acute Toxicity. Acute toxic effects of nickel compounds have been observed after high exposures in accidents. Erroneous drinking of nickel salts caused headache, vomiting, abdominal pain, diarrhea, and other symptoms, which lasted for about one week [41]. Accidental inhalation of soluble nickel compounds caused headache, cough, and, at higher exposure, also lung edemas and fibroses. Symptoms were more pronounced after acute exposure to nickel tetracarbonyl [36]. With experimental animals inhalation of nickel carbonyl also caused kidney failure [29]. Lethal doses of various nickel compounds derived from animal experiments are listed in Table 4. The sparingly soluble species nickel metal powder, nickel oxide, and nickel sulfides exert a very low toxicity in short-term exposures. However, this does not hold for chronic toxicity (see below).

Table 4. Acute oral toxicity of soluble nickel salts in experimental animals (data compiled from [29, 43, 44])

Compound	Species	LD_{50} (mg Ni/kg body mass)
Nickel acetate	rat	350
	mouse	420
Nickel chloride	rat	200
Nickel sulfate	dog	25 – 50
	pig	250
	chicken	300
	rat	300
Nickel oxide	rat	> 5000
Nickel subsulfide	rat	> 5000
Nickel sulfide	rat	> 5000
Nickel metal powder	rat	> 9000

Chronic Toxicity.

Skin. Dermal exposure to nickel metal and nickel salts results in a specific nickel contact dermatitis which was first observed in 1899 in workers in electrolytic plating facilities, and later in hairdressers and medical employees using nickel-plated tools like scissors, forceps, and other medical instruments and in dental technicians abrading dental nickel alloys [45]. A high incidence of nickel allergic dermatitis is observed in the general population after skin contact with nickel-plated jewelry, jeans buttons, or watches. Highest incidences are found in people wearing pierced jewelry [46]. For some decades, 5% of all eczemas registered in the general population were attributed to dermal nickel exposure, but due to preventive measures in the last decade the prevalence of this disease is declining considerably [47]. Nickel dermatitis is caused by pure nickel and high-nickel alloys only, but not by dermal contact with objects made from stainless steel with its lower nickel content.

Respiratory Organs. Whereas the nickel concentrations in ambient air usually are very low, high air concentrations have been experienced in nickel producing and processing industries. Exposure to elevated concentrations of sparingly soluble nickel sulfides and oxides was frequent in nickel mining and smelting, and exposure to soluble nickel compounds was high in nickel refining and nickel electrolytic plating plants. Two types of health effects were registered with nickel workers: inflammatory

symptoms and cancer, both of the respiratory tract.

Nonmalignant Effects. The highest incidence of inflammatory diseases was observed with workers exposed to soluble nickel salts. The symptoms comprise inflammation and dysplasia of the nasal epithelium, pneumonia, and lung fibrosis [29, 43].

Carcinogenicity. Nickel compounds are consistently classified as human carcinogens by various national and international agencies, whereas nickel metal is regarded as carcinogenic to humans only by some organizations (Table 5).

Nickel Metal. The epidemiological evidence for the carcinogenicity of nickel metal is blurred by coexposure to other nickel compounds. Cohorts of workers exposed to high concentrations of nickel metal dust but coexposed to oxidic and sulfidic nickel exhibited elevated incidences of nasal and lung cancer [43]. A large number of workers manufacturing high-nickel alloys in the USA showed an enhanced mortality from lung cancer when the total U.S. population was taken as control, but this correlation was not significant if the local population served as control [49]. In experimental studies, nickel metal powder caused local carcinomas in rats after intraperitoneal injection and intratracheal instillation [50, 51].

Soluble Nickel Salts. The classification of soluble nickel compounds as carcinogenic to humans is based on elevated incidences of nasal and lung cancer in nickel refinery workers who had been exposed predominantly to soluble and to a lesser extent to insoluble nickel compounds. In a Norwegian factory where the fraction of soluble nickel in the air was 90%, high incidences of lung cancer were observed, which were related to the atmospheric concentration of soluble nickel in the range between 1 and 15 mg Ni/m^3 [52]. The epidemiological data are seemingly contradicted by the negative result of an experimental animal study in which no tumors were induced by inhalation of nickel sulfate up to a concentration of 0.11 mg Ni/m^3 in rats and 0.22 mg Ni/m^3 in mice [53]. This disagreement may be interpreted by taking into account that the concentrations in the animal study were confined to much lower values than the human exposures because of the onset of severe inflammatory effects at the lower experimental doses [53].

Sulfidic and Oxidic Nickel. Although in industry there never has been pure exposure to either sulfidic or oxidic nickel, some cohorts of nickel smelter workers were predominantly exposed to nickel sulfides and other cohorts predominantly to nickel oxides. Both cohorts showed significantly enhanced incidences of nasal and lung carcinomas [54], and therefore both sulfidic and oxidic nickel have been classified as human carcinogens. This classification is supported by the carcinogenicity of nickel subsulfide and nickel oxide in animal experiments [53].

Toxicity to Other Organs.

Nephrotoxicity. There is limited evidence for nephrotoxicity of soluble nickel compounds in highly exposed workers [55] and after oral uptake of soluble nickel salts by experimental animals [29]. Inhalation of nickel tetracarbonyl caused kidney failure in rats [29].

Reproductive Toxicity. In experiments with rats, oral and intraperitoneal administration of soluble nickel salts interfered with reproduction. Nickel sulfate caused diminished fertility, decreased number and birth weight of pups, and a pattern of anomalies (malformation of eyes, lung, kidney, bones, and palatal clefts) [43]. Inhalation of nickel tetracarbonyl induced teratogenic effects in rats [56].

Genotoxicity. Nickel compounds are only weakly genotoxic. Nickel salts were inactive in nearly all bacterial mutagenicity assays and only weakly mutagenic in mammalian cell tests. Only elevated (millimolar) concentrations of soluble nickel salts induced chromosomal aberrations, sister chromatid exchanges, and DNA damage in mammalian cells in vitro [43]. However, in cellular systems nickel ions enhanced the genotoxicity of alkylating agents and UV irradiation, because they inhibit the repair of DNA damage induced by these agents [57].

Environmental Toxicology.

Effects on Microorganisms. Nickel is an essential element for anaerobic, hydrogen-producing bacteria [58]. The toxicity of nickel

Table 5. Classification of nickel and nickel compounds as carcinogens

Agency	Substances	Classification
IARC 1990 [43]	nickel compounds	1 (carcinogenic to humans)
	nickel metal	2B (possibly carcinogenic to humans)
DFG 2001 [48]	nickel and nickel compounds	1 (causes cancer in humans)
EU	nickel metal	3 (possibly carcinogenic to humans)
	nickel carbonate	3 (possibly carcinogenic to humans)
	nickel dioxide	1 (carcinogenic to humans)
	nickel monoxide	1 (carcinogenic to humans)
	nickel sulfate	3 (possibly carcinogenic to humans)
	nickel sulfide	1 (carcinogenic to humans)
	nickel tetracarbonyl	3 (possibly carcinogenic to humans)
ACGIH 2003	nickel subsulfide	A1 (confirmed human carcinogen)
EPA 2003	nickel refinery dust	A (human carcinogen)
	nickel carbonyl	B2 (probable human carcinogen)
	nickel subsulfide	A (human carcinogen)
NTP (National Toxicology Program), USA 2002	nickel metal	reasonably anticipated to be human carcinogen
	nickel compounds	known human carcinogens

Table 6. Synopsis of limit values for nickel and nickel compounds (as elemental nickel).

Description	Limit values	Source
Occupational limit values, nickel metal dust	0.5 mg/m^{3}1.0 mg/m^3	France, Germany, UKOSHA 2003
Occupational limit values, insoluble compounds (oxidic and sulfidic nickel)	0.5 mg/m^{3}1.0 mg/m^3	France, Germany, UKOSHA 2003
Occupational limit values, soluble nickel salts	0.05 mg/m^{3}0.1 mg/m^{3}1.0 mg/m^3	GermanyFrance, UKOSHA 2003
Occupational limit values, nickel tetracarbonyl	0.15 mg/m^{3}0.3 mg/m^{3}0.007 mg/m^3	GermanyFranceUK, OSHA 2003
General ambient air	0.5 mg/m^3	TA Luft 2002
Effluent discharge	8 – 100 µg/L	EC directive 76/464
Sewage sludge	300 – 400 mg/kg d.m.200 mg/kg d.m.	EC directive 86/278German KlärschlammVO 1992
Soil	30 – 75 mg/kg d.m.15 – 70 mg/kg d.m., depending on soil type	EC Directive 86/278German BbodSchV 1999
Drinking water	0.05 mg/L0.02 mg/L0.1 mg/L	EC Directive 80/778Germany TrinkwasserVO 2001US EPA 2002
Food, recommended limit for uptake of soluble nickel	1 mg/d	US National Academy of Sciences 2001 [62].

to bacteria, yeasts, and fungi differs considerably [59]. The growth of eubacteria is inhibited by nickel concentrations of 5 - 30 µg Ni/L, whereas filamentous fungi are inhibited by 5 - 1000 µg Ni/L. In acid environment the toxicity of nickel compounds to microorganisms is elevated because of enhanced solubilization from complexes.

Effects on Plants. Nickel is essential for the growth of those plants which have been investigated in this respect. Terrestrial plants accumulate nickel and on average contain between 0.3 and 6 mg/kg d.m. Soil concentrations of more than 70 mg/kg d.m. are generally phytotoxic with the exception of plants adapted to nickel-rich soils. Aquatic algae tolerate higher concentrations of nickel and may accumulate the element up to 1000-fold, corresponding to 150 mg/kg d.m. [60].

Regulations and Guidelines. The qualitative classifications of nickel and nickel compounds with respect to carcinogenicity are summarized in Table 5. The quantitative risk of cancer incidence was estimated by the WHO [61] by a unit risk of 4×10^{-4} per µg Ni/m^3. A synopsis of regulations, guidelines an legislation for nickel is given in Table 6.

1. Introduction

Niobium [*7440-03-1*], Nb, atomic number 41, A_r 92.91, is also known as columbium, Cb, in the United States. There are many artificial radionuclides, but only one known natural nonradioactive isotope, ^{93}Nb. The electronic configuration of the ground state is $4s^2p^6d^3\ 5s^2$, which explains the existence of the oxidation states +2 to +5.

Niobium was discovered by HATCHETT in 1801 in the mineral columbite and was named columbium. In 1844 the name niobium was proposed by ROSE.

2. Properties

2.1. Physical Properties

Some important physical properties of niobium metal are as follows [1–3]:

Density at 20 °C	8.57 g/cm^3
Crystal structure	body-centered cubic ($a = 3.3 \times 10^{-10}$ m)
mp	2468 ± 10 °C
bp	4927 °C
Linear coefficient of thermal expansion	6.892×10^{-6} K^{-1}
Specific heat	0.26 kJ kg^{-1} K^{-1}
Latent heat of fusion	290 kJ/kg
Latent heat of vaporization	7490 kJ/kg
Thermal conductivity at 0 °C	0.533 Wcm^{-1} K^{-1}
Electrical resistivity at 0 °C	15.22 μΩ · cm
Temperature coefficient 0 – 600 °C	0.0396 K^{-1}
Electrochemical equivalent	0.19256 mg/C
Standard electrode potential E° Nb/Nb^{+5}	−0.96 V
Magnetic susceptibility at 25 °C	2.28×10^{-6}
Superconductivity T_C	9.13 K
Spectral emissivity at 650×10^{-10} m (at 2003 K)	2.28×10^{-6}
Ionisation potential	6.67 eV
Work function	4.01 eV

The mechanical properties, like those of most refractory metals, are influenced by the purity of the metal, the production method, and the mechanical treatment. Even small amounts of interstitial impurities increase the hardness and strength but reduce the ductility. Some important mechanical properties of commercial niobium are as follows [4]:

Annealed niobium	
Ultimate tensile strength	195 MPa
Yield strength	105 MPa
Elongation	30 % +
Reduction in area	80 % +
Hardness	60 HV
Poisson's ratio	0.38
Strain hardening exponent	0.24
Elastic modulus	
tension	103 GPa
shear	17.5 GPa

Table 1. Niobium deposits [6]

Location	Capacity, 10^6 kg Nb_2O_5	Ore grade	Reserves, 10^6 t Nb_2O_5	Production, 10^6 kg Nb_2O_5
Araxa, Brazil	24.75	3.0	500+	9.45
St. Honore, Quebec	3.15	0.7	11	3.15
Catalao, Brazil	2.48	1.5	50	2.48
Nigeria	0.9			
Thailand	0.45 – 0.9			
Zaire	pilot scale	2 – 3	extensive	0.23

Ductile – brittle transition temperature	< 147 K
Recrystallization temperature	800 – 1000 °C
Cold worked niobium	
Ultimate tensile strength	585 MPa
Elongation	5 %
Hardness	150 HV

2.2. Chemical Properties

Niobium is very resistant to most organic and inorganic acids, with the exception of HF, at temperatures up to 100 °C [1]. Concentrated sulfuric acid above 150 °C causes embrittlement. The resistance towards alkaline solutions is lower. Because niobium has a marked tendency to form oxides, hydrides, nitrides, and carbides, its use in air is limited to temperatures up to ca. 200 °C.

3. Occurrence

Niobium occupies the 33rd place in order of natural abundance, being present in the earth's crust at 24 µg/g. It is thus more common than cobalt, molybdenum, or tantalum.

The most important niobium mineral is pyrochlore, a compound with the general formula $(Ca,Na)_{2-m}Nb_2O_6\ (O,OH,F)_{1-n} \cdot x\ H_2O$. The lattice positions of Na and Ca can also be occupied by Ba, Sr, rare earths, Th, and U. The latter two elements are responsible for the radioactivity of some pyrochlore concentrates.

Two types of niobium ore deposits are known. In primary deposits, the pyrochlore is always interstratified in carbonatites. This is so in the Canadian deposits at Niobec and Oka, in which calciopyrochlore is interstratified in dolomite. The ore contains 0.5 – 0.7 % niobium pentoxide. In the important secondary Brazilian deposits at Araxa and Catalao, the niobium content of the carbonate minerals has been considerably enriched by weathering. Here, the ore is present in combination with apatite, iron oxide, and barite and contains about 3 % Nb_2O_5, 46 % Fe_2O_3, 17 – 18 % BaO, and 1.5 % P as apatite [5]. Table 1 shows the average Nb_2O_5 capacity, the production, and the reserves of various deposits [6]. In addition to the sources listed in Table 1, other, potential sources exist in Canada, Africa, Brazil, China, the United States, and the former Soviet Union.

The most commercially important deposits are in Brazil, Canada, Nigeria, and Zaire. World reserves are estimated to be 4.1×10^6 t Nb, of which 78 % are in Brazil. The Canadian reserves are estimated at 0.12×10^6t.

The second most important niobium mineral is columbite, $(Fe,Mn)(Nb,Ta)_2O_6$, in which niobium is nearly always present with tantalum. These ores are referred to as columbites if the Nb_2O_5 content is greater than that of Ta_2O_5, otherwise as tantalites. Columbites and tantalites contain at least 60 % combined pentoxides. These minerals occur as primary deposits in granites and pegmatites, or in alluvial secondary deposits. Table 2 lists the chemical compositions of various niobium and tantalum minerals [7].

Columbites are mined in Australia, Brazil, Nigeria, Malaysia, and Zaire. Since the discovery of the enormous deposits of pyrochlore in Brazil, world production of columbite has decreased considerably. This trend could change when the extraction of columbite as a by-product of tin extraction is started with the Pitinga deposits in Brazil [8]. The discovery of large deposits of pyrochlore in South Greenland (Motzfeld Center) was reported in 1986.

A further source of niobium is provided by tantalum – niobium slags from tin production, since columbites and tantalites are often associated with cassiterite; niobium and tantalum

Table 2. Chemical composition of the principal niobium-bearing minerals, % [7]

Mineral	Nb_2O_5	Ta_2O_5	TiO_2	Fe	MnO	SnO_2
Pyrochlore, $NaCaNb_2O_6F$	40 – 65	2	1 – 6	2		
Columbite, $(Fe,Mn)(Nb,Ta)_2O_6$	40 – 75	1 – 40	0.5 – 3	10 – 20	2.6	2
Tantalo-columbite, $(Fe,Mn)(Nb,Ta)_2O_6$	25 – 60	20 – 50	0.5 – 3	10 – 20	2.6	2
Tantalite, $(Fe,Mn)(Ta,Nb)_2O_6$	2 – 40	42 – 84	0.5 – 3	10 – 20	2.6	2
Microlite, $Ca_2(Ta,Nb)_2O_6(OH,F)$		60 – 70				

concentrate in the slags as oxides. The niobium and tantalum pentoxide content of various tin slags is given in Table 3 [9]. Niobium and tantalum are also found in rare minerals such as stibiocolumbites $(Sb,Nb)TaO_4$, fergusonites $(Re^{3+})NbO_4$, and euxenite $Y(Nb,Ti)_2O_6$. The last two of these, however, are of no commercial significance.

Zaire	5	9

4. Processing of Niobium Ores

4.1. Winning of Pyrochlore Concentrates

Concentrates containing 50 – 60 % Nb_2O_5 are obtained from pyrochlore-containing carbonatites or weathered ores by conventional beneficiation processes such as crushing, grinding, magnetic separation, and flotation. Brazilian concentrates (Araxa) are also treated chemically to remove lead, phosphorus, and sulfur. The raw concentrate is roasted in the presence of calcium chloride and calcium oxide in a rotary furnace at 800 – 900 °C, and the product is leached with hydrochloric acid. In the case of Brazilian pyrochlore, this procedure also leads to replacement of barium by calcium [10].

4.2. Treatment of Pyrochlore Concentrates

Whereas pyrochlore from Araxa can be converted directly to ferroniobium, pyrochlore concentrates from other sources must first be chemically pretreated before niobium can be obtained. Some well-known processes are treatment with concentrated sulfuric acid or with molten soda. Reductive chlorination of pyrochlore at ca. 1000 °C produces volatile chlorides of niobium and other metals. These processes are, however, generally regarded as uneconomical. This is also true of the process in which digestion of pyrochlore with mixtures of hydrofluoric and sulfuric acids is followed by solvent extraction [11].

4.3. Production of Niobium Oxide from Columbites and Tantalites

4.3.1. Extraction Processes

Niobium and tantalum always occur together in columbites and tantalites and must be separated not only from the other elements present but also from each other. The industrial separation of tantalum from niobium has long been carried out by the Marignac process of fractional crystallization of potassium heptafluorotantalate and potassium heptafluoroniobate [12]. This expensive process of precipitation and crystallization, which is also environmentally unacceptable, has been abandoned, together with the long established Fansteel process [12], in favor of processes based on solvent extraction.

Tantalite and columbite, either naturally occurring or synthetically produced as concentrates from tin slags [13, 14], are digested with hydrofluoric and sulfuric acids at elevated temperature. The accompanying elements are dissolved along with the tantalum and niobium, which form the complex heptafluorides H_2TaF_7 and H_2NbOF_5 or H_2NbF_7. After filtering off the insoluble residue (fluorides of alkaline earth and rare earth metals), the aqueous solution of

Ta – Nb in hydrofluoric acid is extracted in several continuously operated mixer-settlers with an organic solvent, e.g., methyl isobutyl ketone (MIBK) [15–17]. The complex fluorides of niobium and tantalum are extracted by the organic phase, whereas most of the impurities and other elements, such as iron, manganese, titanium, etc., remain in the aqueous phase. In practice, $Nb_2O_5 + Ta_2O_5$ concentrations of 150 – 200 g/L in the organic phase are used. The organic phase is washed with 6 – 15 N sulfuric acid and then reextracted with water or dilute sulfuric acid to obtain the niobium. The aqueous phase takes up the complex fluoroniobate and free hydrofluoric acid, while the complex fluorotantalate remains dissolved in the organic phase. The aqueous niobium solution is reextracted with a small amount of MIBK to remove traces of tantalum. The resulting organic phase is returned to the combined tantalum – niobium extraction stage. Gaseous or aqueous ammonia is added to the aqueous niobium solution to precipitate niobium oxide hydrate. Crystallization of K_2NbF_7 can only be achieved in strong hydrofluoric acid solution; therefore, it is only carried out on a small scale because of the high costs arising from the increased consumption of hydrofluoric acid.

The tantalum is reextracted from the organic phase with water or dilute ammonia solution, and tantalum oxide hydrate is precipitated by ammonia, or potassium salts are added to produce K_2TaF_7, which is used in the production of tantalum metal.

The oxide hydrates are collected by filtration, dried, and calcined at up to 1100 °C. Variation of the conditions of precipitation, drying and calcination produces different particle sizes, giving oxides suitable for various applications. Depending on the quality requirements, the calcination is carried out in directly or indirectly heated chamber or rotary furnaces. The nature of the furnace lining has considerable influence on purity.

Sophisticated process control and optimization enable niobium and tantalum to be produced with high yield (> 95 %) and purity (> 99.9 %).

A number of alternative extraction media have been reported in the literature, most of which have never been used in industry, except for tributyl phosphate (TBP) [18] and tri-*n*-octylphosphine oxide (TOPO) [19].

Figure 1 (see next page) shows the flow diagram of an industrial installation for the processing of tantalum –niobium raw materials [20].

4.3.2. Chlorination

The chlorination process is a modern alternative to the extraction process. There are two versions: reductive chlorination of natural and synthetic raw materials, and chlorination of tantalum – niobium ferroalloys.

In reductive chlorination, the ore or concentrate is pelletized with coal/coke and pitch, dried, and reacted in a stream of chlorine at 900 °C. The nonvolatile alkaline earth metal chlorides remain behind, while the readily volatilized tetrachlorides of silicon, tin, titanium, the pentachlorides $NbCl_5$ and $TaCl_5$, and $WOCl_4$ are distilled off and fractionated. The waste gas, which contains large amounts of phosgene and chlorine, must be rigorously purified.

The chlorination of ferroalloys is much simpler and more economical [21,22]. Ferroniobium or ferroniobium – tantalum are produced by the aluminothermic or electrothermic process, size reduced, and fed together with sodium chloride into a $NaCl - FeCl_3$ melt. The chlorinating agent is $NaFeCl_4$. Chlorine is passed into the melt, continuously regenerating $NaFeCl_4$. The following overall reactions take place:

$$FeTaNb + NaCl + 7\ NaFeCl_4 \rightarrow Ta/NbCl_5 + 8\ NaFeCl_3$$

$$8\ NaFeCl_3 + 4\ Cl_2 \rightarrow 8\ NaFeCl_4$$

The reaction temperature of 500 – 600 °C is much lower than that required for reductive chlorination. The volatile chlorides are evolved from the molten salt bath. The boiling points of $NbCl_5$, $TaCl_5$, and $WOCl_4$ lie between 228 and 248 °C, and these compounds must therefore be separated by means of a distillation column.

The chlorination of ferroalloys produces very pure niobium pentachloride and tantalum pentachloride in tonnage quantities. The $NbCl_5$ contains less than 30 µg/g Ta, and other metallic impurities only amount to 1 – 2 µg/g. Niobium pentachloride is an intermediate in the production of oxides and organometallic compounds, and is the starting material for production of niobium powder and for chemical vapor deposition (CVD) of niobium coatings.

Figure 1. Flow diagram for the processing of tantalum – niobium raw materials [20]

5. Niobium Compounds

5.1. Oxides

Niobium pentoxide [*1313-96-8*], niobic acid, Nb_2O_5, *mp* 265 °C, *bp* 1495 °C, is a colorless powder that can only be dissolved by fusion with acidic or alkaline fluxes such as NaOH or $KHSO_4$, or in hydrofluoric acid. It is prepared by hydrolyzing solutions of alkali-metal niobates, niobium alkoxides (e.g., $Nb(OC_2H_5)_5$), or niobium pentachloride, or by precipitation from hydrofluoric acid solutions with alkali-metal hy-

droxides or ammonia. Depending on the method used, the oxide hydrate formed is either a gel that is difficult to filter or is flocculent. The oxide hydrate is filtered, washed, and calcined at 800–1100 °C. The temperature and treatment time determine which of the various crystalline modifications is formed. Nearly all the phase changes are irreversible [23–25].

Uses. Niobium pentoxide is used in metallurgy, for the production of hard materials, in optics, and in electronics. Hydrated Nb_2O_5, which can be regarded as an isopolyacid, has a high surface acidity, and catalyzes the polymerization of alkenes, e.g., propylene [26].

Various applications require different qualities of Nb_2O_5. For the electrothermic and metallothermic manufacture of niobium metal or its alloys, technical quality niobium pentoxide ($>98-99\,\%$) is suitable. For higher quality requirements, chemically pure niobium pentoxide ($>99.7\,\%$) is used.

In optics, niobium pentoxide is used as an additive to molten glass to prevent devitrification and to control properties such as refractive index and light absorption [27]. Optical grade niobium pentoxide, with a purity of $>99.9\,\%$, must be free from colored impurities such as chromium, nickel, iron, manganese, etc.

Extremely stringent purity requirements apply to Nb_2O_5 used in the manufacture of $LiNbO_3$ [*12031-63-9*] or $KNbO_3$ [*12030-85-2*] single crystals (Nb_2O_5 ultra pure grade, $>99.995\,\%$). These compounds are used for electroacoustic and electrooptical components such as modulators, frequency doublers, and wave filters [28, 29].

Ceramic grade niobium pentoxide, used for making dielectric materials, must be manufactured with a special particle size distribution. This market sector will demand greatly increased quantities of niobium pentoxide if the development of the new class of ferroelectric perovskites (relaxors) is successful, e.g., $Pb(Mg_{1/3}\,Nb_{2/3})O_3$ for the manufacture of ceramic capacitors [30–32].

Details of the various commercial qualities of niobium pentoxide are given in Table 4 (see next page) [20].

5.2. Halides

Niobium pentachloride [*10026-12-7*], $NbCl_5$, M_r 270.2, *mp* 209.5 °C, *bp* 249 °C, is now produced exclusively by chlorination of ferroniobium, niobium metal, or niobium scrap (see Section 4.3.2.).

Niobium pentachloride forms strongly hygroscopic yellow crystals that react with water to form $NbOCl_3$ or $Nb_2O_5 \cdot x\ H_2O$. The pentachloride is very soluble in dry ethanol, tetrahydrofuran, and benzene. Alcoholic solutions of niobium pentachloride are used in the production of niobium alkoxides such as the pentaethoxide, $Nb(OC_2H_5)_5$, from which micronized niobium pentoxide is produced [33]. Pure niobium pentachloride is used for large scale production of niobium pentoxide and niobium metal.

Niobium tetrachloride [*13569-70-5*], $NbCl_4$, sublimes between 350 and 400 °C. Niobium trichloride [*13569-59-0*], $NbCl_3$, disproportionates between 900 and 1000 °C. Niobium trichloride and niobium dichloride [*13777-09-8*], $NbCl_2$, are formed by reduction of $NbCl_5$ with hydrogen, but are of no industrial importance.

Niobium oxychloride [*13597-20-1*], $NbOCl_3$, M_r 215.28, is a colorless, crystalline compound that sublimes at 400 °C and partly decomposes into niobium pentoxide and niobium pentachloride on further heating.

Niobium pentafluoride [*7783-68-8*], NbF_5, M_r 187.91, *mp* 72 °C, *bp* 236 °C, can be prepared by fluorination of niobium pentachloride or niobium metal with fluorine or anhydrous HF. The reaction of Nb_2O_5 with aqueous HF yields fluoroniobic acids of various compositions (e.g., H_2NbF_7 or H_2NbOF_5), depending on the acid concentration. They are soluble in organic solvents and consequently play an important part in the separation of tantalum from niobium by solvent extraction.

5.3. Carbides and Hard Materials

The carbides, borides, silicides, and nitrides of niobium are metallic hard materials [34]. Some of their physical properties are listed in Table 5. Only the carbides are commercially important.

Table 4. Commercially available niobium oxides [20]

Niobium Carbides (→ Carbides, Chap. 2.4.). The niobium – carbon phase diagram [35] indicates the existence of a face-centered cubic compound, NbC, which melts without decomposition at 3600 °C with a broad region of homogeneity, and of Nb_2C, which has a peritectic melting point. Only NbC has practical applications. In addition to its original use as a grain growth inhibitor in tungsten carbide – cobalt hard materials, it is now used mainly as solid solutions with titanium carbide, tantalum carbide, and tungsten carbide for cutting tools. The precise effect of niobium on the composition, microstructure, and properties of these hard materials is not yet fully understood [36]. In practice, up to 50 % of the more expensive TaC can be replaced by NbC without appreciably affecting the hardness or fracture strength [37].

Production, like that of TaC, is by carburizing the oxide, hydride, or metal at 1500 °C in a carbon tube furnace, vacuum furnace, or in the

presence of a molten metallic menstruum such as iron or aluminum. Some of the physical properties of niobium carbides are given in Table 5.

Niobium Borides. The niobium – boron phase diagram [38] shows the existence of Nb_3B_2, NbB, Nb_3B_4, and NbB_2. However, these high-melting, very hard materials, have no industrial uses. Table 5 lists their physical properties.

Niobium silicides, Nb_4Si, Nb_5Si_3, and $NbSi_2$, are produced by the silicothermic reduction of Nb_2O_5 or from the elements by sintering, pressure sintering, or fusion in an electric arc furnace. Some physical data are given in Table 5. These compounds are not used industrially.

Niobium Nitrides. Various nitride phases, with regions of homogeneity varying in distinctness, are obtained by heating niobium metal or mixtures of niobium oxide and carbon in a stream of ammonia or nitrogen [39]. Niobium metal can be produced by thermal decomposition of NbN in high vacuum. The pure nitrides have not as yet found any industrial application. Table 5 lists some of the physical properties of niobium nitrides.

Niobium Hydrides. On heating niobium in a pure hydrogen atmosphere to 350 – 500 °C, hydrogen (ca. 44 atom %) is absorbed, causing expansion of the lattice and embrittlement. Apart from the $NbH_{0.9}$ [*13981-86-7*] thus formed, the hydride Nb_4H_3 [*56941-03-8*] [40,41] and the unstable dihydride NbH_2 [*13981-96-9*] [42] are also known.

The reversible uptake and release of hydrogen by NbH is used in industry as a means of producing niobium powder from compact niobium, e.g., scrap or ingots. The metal is first hydrogenated, then ground, and finally dehydrogenated in a vacuum furnace or under an inert gas.

6. Niobium Metal

The industrial production of niobium is usually carried out by the reduction of the pentoxide or halides. The crude metal is then refined electrothermally.

6.1. Reduction of Niobium Pentoxide

Niobium pentoxide is reacted with carbon, aluminum, or silicon at high temperature. In the carbothermic process, niobium pentoxide is mixed with carbon black, and the mixture is pelletized and reduced in a vacuum furnace in a two-stage process at 1950 °C:

$$Nb_2O_5 + 7\,C \rightarrow 2\,NbC + 5\,CO$$
$$5\,NbC + Nb_2O_5 \rightarrow 7\,Nb + 5\,CO$$

The reaction takes place with the formation of NbC, Nb_2C, NbO_2 and NbO [43,44]. A crude product containing oxygen and carbon is produced, which must be refined in further high-temperature processes.

The following one-stage carbonitrothermic reduction of niobium pentoxide has been successfully carried out on the pilot-plant scale. A pelletized mixture of niobium pentoxide and carbon black is reacted in a stream of ammonia in an induction furnace at 1570 ± 20 °C to form niobium nitride, NbN, which is then thermally decomposed in high vacuum at 2000 – 2100 °C. However, the process does not yet appear to have been used on an industrial scale [45,46].

Over 90 % of niobium metal is produced by aluminothermic reduction:

$$3\,Nb_2O_5 + 10\,Al \rightarrow 6\,Nb + 5\,Al_2O_3$$

Niobium metal produced by this process is designated ATR niobium. In general, an excess of aluminum is used, producing a niobium – aluminum alloy which is melted in a vacuum, electric arc, or electron beam furnace to produce low-oxygen, carbon-free niobium [47,48]. The amount of excess aluminum determines the yield of niobium and its oxygen content [49].

The silicothermic reduction of niobium pentoxide can lead to silicide formation, and the thermodynamics of this reaction are less favorable. This process is therefore not in regular use.

6.2. Reduction of Halides

The reduction of niobium pentachloride can be achieved with hydrogen at 600 – 650 °C [50]. Alternatively, niobium pentachloride vapor is reduced with hydrogen in a fluidized bed furnace at 750 – 1050 °C [51] or in a hydrogen plasma above 2000 °C [52]. Metallothermic reduction with sodium or magnesium has also been reported [53]. The company TOHO Titanium Corporation has commissioned a plant with a capacity of 30 t/a niobium in which niobium pentachloride is reduced by magnesium [54]. A reduction process with zinc using the auxiliary metal bath technique is also known [55]. In contrast to the production of tantalum, the reduction of the fluoroniobates K_2NbF_7 and K_2NbOF_5 has not become industrially significant.

Very pure niobium can be obtained by electrowinning from oxygen-free molten salt systems with double fluorides or chlorides as the source of metal [56]. These molten salts are very corrosive and the current efficiencies are low. For these reasons, molten salt electrowinning of metallic niobium is not carried out commercially.

6.3. Refining

Crude niobium must be refined in order to remove impurities introduced either from the raw materials or during the treatment stages.

Purification can be achieved by high-temperature treatment because the melting point of niobium (2497 °C) is so high that most other elements can be removed by vaporization. Niobium is extremely reactive towards all but the inert gases [57], and melting must therefore always be carried out in a high or ultra-high vacuum or under a pure inert gas to minimize the concentration of harmful interstitial foreign atoms.

In comparison to the classical sintering and electric arc melting processes, electron beam melting (EBM) has considerable technical advantages for the production of pure metal.

The vaporization of the impurities can be controlled in each melting cycle by[58,59]:

1) Optimizing the melting rate,
2) Maintaining the bath in a liquid state for a long period, and
3) Controlled superheating of the molten metal.

Sufficient refinement cannot be achieved with one melting cycle only, so that in practice the solid ingot produced must be remelted. The melting rate (kg/h Nb) for the first melt (main refining step) depends on the raw material and

is lower for ATR niobium because of the high content of aluminum and NbO that must be evaporated compared with compacted granular niobium. Further development of the plasma melting technique would enable a simple plasma furnace to be used for the first melting operation [60, 61]. In the second and third melting cycles, the melting rate can be increased by a factor of 3 – 4, depending on the specification of the material.

Optimization of the equipment used in the electron beam melting process, leading to reduction in residual gas pressure and leakage rate, has enabled standard quality niobium to be produced from ATR niobium on a large scale with only two melting cycles [62].

The electron beam melting and remelting technique enables niobium metal with less than 50 µg/g interstitial impurities to be produced for high-frequency superconductors. Figure 2 shows the concentration of interstitial impurities (O, N, and C) as a function of the number of melting cycles [63].

Figure 2. Contents of interstitial impurities (O, N, and C) of an electron beam melted niobium ingot as a function of the number of melting cycles [63]

Ultra-high purity niobium can be obtained from metal melted by the EBM method by a series of additional sophisticated process steps, including electrorefining and electron beam zone melting, followed by high-temperature treatment in high vacuum. By these methods, niobium metal can be prepared with metallic impurities in the parts per billion range and with interstitial impurities < 1 ppm [64].

6.4. Uses

Niobium has good resistance towards corrosive chemicals [4, 65] even at high temperatures, and is therefore used in the construction of chemical equipment, though it is not quite so resistant as tantalum. The process of oxide dispersion hardening of niobium with titanium dioxide gives a material which can be used both for chemical equipment and for medical implants subjected to high mechanical loading [66]. High-niobium alloys such as KBI 40/41 [67] can also be used under these conditions, for which formerly the more expensive metal tantalum had to be used.

Because niobium has a low neutron capture cross-section and is unusually resistant towards corrosion by liquid sodium, it is used in the pure state or as the alloy NbZr1 in the nuclear industry for the production of fuel element cans. This alloy is also used for the sealing caps of sodium vapor lamps.

World consumption of niobium for the production of superconducting materials, such as Nb_3Sn and NbTi is estimated to be 60 – 70 t/a.

The addition of niobium to titanium – aluminum alloys imparts the ductility needed to fabricate this material for the aircraft and space industry [68].

Other newly developed alloys C 103 (NbHf10Ti1) and Nb 752 (NbW10Zr25) combined with a special coating technique enable niobium to be used in the manufacture of nozzles and combustion chambers for rocket propulsion [69].

7. Ferroniobium

Approximately 85 – 90 % of the total niobium production is used in the steel industry in the form of iron – niobium alloy (ferroniobium) containing 40 – 70 % niobium. Depending on the application, the alloy can also contain small amounts of Ta (ferroniobium – tantalum), e.g., FeNb65Ta2, which contains 65 % Nb and 2 % Ta. Other alloy specifications are given in [70].

7.1. Production

Ferroniobium is usually produced by aluminothermic reduction of niobium oxide ores, with the addition of iron oxides if the niobium ore used contains insufficient iron. The starting materials are mainly columbites and pyrochlore concentrates.

The enthalpy of the reaction between Nb_2O_5 and Al is −276.1 kJ/mol Al, which is lower than the threshold value for self-sustaining aluminothermic reactions. The mixture must therefore either be preheated or mixed with oxygenreleasing compounds such as BaO_2, CaO_2, $KClO_4$, $KClO_3$ or $NaNO_3$.

Concentrates with lower percentages of niobium (ca. 40 %) can also be treated by the aluminothermic process in an electric arc furnace. Also, a two-stage electroaluminothermic process for the production of ferroniobium from columbite has been developed [71].

The method of operation is to charge the mixture of niobium concentrate with the additives to refractory lined reaction vessels. Either the whole mixture is reacted, or a small amount is set aside, ignited with a special exothermic mixture, and added to the bulk mixture. The molten reaction product is allowed to solidify in the furnace, and the block of metal separates from the slag. After cooling, it is broken into pieces of the required size.

In the aluminothermic process operated at Araxa, Fe – Nb blocks of metal up to 11 t in weight are produced. The yield of niobium metal is 96 – 97 %. The typical composition of a reaction charge is as follows:

Pyrochlore concentrate	18 000kg (60 % Nb_2O_5)
Iron oxide	4000 kg (68 % Fe)
Aluminum powder	6000 kg
Fluorspar	750 kg
Lime	500 kg

The reaction gives ca. 11 000 kg of ferroniobium of composition:

Nb	66.0 %
Fe	30.5 %
Si	1.5 %
Al	0.5 %
Ti	0.1 %
P	0.1 %
S	0.04 %
C	0.08 %
Pb	0.02 %

and ca. 20 000 kg of slag containing:

Al_2O_3	48.0 %
CaO	25.0 %
TiO_2	4.0 %
BaO	2.0 %
Re_2O_3	4.0 %
Nb_2O_5	trace
ThO_2	2.0 %
U_3O_8	0.05 %

Special niobium alloys, e.g., nickel – niobium, cobalt – niobium, aluminum – niobium and chromium – niobium, are also manufactured by the aluminothermic process. For these alloys, which have various niobium contents [72], niobium oxide is the only raw material used.

7.2. Uses of Ferroniobium

Niobium has very marked carbide and nitride forming properties and is therefore mainly used in the production of steels and gray iron [73]. The addition of niobium prevents intercrystalline corrosion in stainless austenitic chromium – nickel steels and improves corrosion resistance, weldability, ductility, and toughness in ferritic chromium steels [74]. Ferroniobium is also used as a trace additive in large quantities for the production of high-strength low-alloy (HSLA) steels used in automobile body manufacture, structural steels, concrete reinforcing steel, and pipelines. Superalloys containing up to 5 % niobium are used for gas turbine components. These materials have high hot strength [75, 76], and mostly have a nickel or copper base. The niobium is added in the form of nickel – niobium or cobalt – niobium.

8. Analysis

Extensive literature on the analytical determination of niobium is available in handbooks and monographs [77–80].

The determination of niobium in raw materials is carried out by X-ray fluorescence [81–83]. For this purpose, test pieces in tablet form are produced by reacting the niobium-containing material with borate to produce a melt, or by compressing it with binders such as wax or boric acid.

For ferroniobium, X-ray fluorescence analysis of HF solutions [84] or borate tablets is used.

For umpire assay, it is usual to separate the niobium from the other material using ion-exchange resins with HF solutions, followed by gravimetric determination [85]. Small niobium contents in steels are determined photometrically [86].

Metallic impurities in niobium pentoxide or niobium metal are determined by atomic absorption spectrometry (AAS) or atomic emission spectrometry (ICP-OES, DCP-OES) in HF solution [87]. Emission spectrum analysis in a d.c. current plasma arc is also used. The nonmetals oxygen, nitrogen, hydrogen, carbon, and sulfur are determined by extraction at high temperature either with a carrier gas or under vacuum, or by combustion analysis in a stream of oxygen [88]. The hydride-forming elements arsenic, antimony, bismuth, selenium, and tellurium can be converted to their hydrides and detected with high sensitivity by the AAS method. The anions Cl^- and F^- are separated by distillation and determined photometrically, by ion-selective electrodes, or by ion chromatography.

In all the above-mentioned methods, the usual limits of detection are from the low µg/g region down to the ng/g region in routine quality testing. For the analysis of ng/g trace impurities it is necessary to separate and concentrate the material [89, 90]. The final determination is carried out using AAS with a graphite furnace, ICP-OES, DCP-OES, or voltammetry. Recently, ICP mass spectrometry has become a powerful additional method for many metallic impurities. Niobium metal is analyzed simply and quickly for metallic and nonmetallic impurities down to the lower ng/g region by glow discharge mass spectrometry (GDMS) [91]. The additional techniques of neutron activation analysis [92, 93] or proton activation analysis [94] are used for verification.

9. Economic Aspects

The world consumption of niobium has, since 1980, reached $16-20\times10^6$ kg Nb_2O_5. The annual rate of increase is ca. 2 %. More than 90 % of total niobium production goes to the steel industry in the form of ferroniobium or niobium alloys, and therefore the demand for niobium is determined by the world market for iron and steel [95]. Figure 3 shows the clear relationship between steel production and niobium demand. Between 1984 and 1988, technical quality niobium pentoxide was marketed in the price range 14.3 – 15.2 \$/kg. The price of standard grade ferroniobium was 14.5 \$/kg Nb. In mid 1987, the price of niobium concentrate (> 65 % $Nb_2O_5 + Ta_2O_5$, 10 : 1) was 5.5 – 6.4 \$/kg Nb_2O_5 CIF Europe. Canadian pyrochlore concentrate was quoted at 5.9 \$/kg Nb_2O_5 FOB.

Figure 3. World niobium consumption compared to world crude steel production from 1972 – 1988 [95].

1. Sodium Nitrate

Sodium nitrate in the form of Chile saltpeter was the most important inorganic nitrogen fertilizer until about 1920; it is the only abundantly occurring mineral nitrate.

1.1. Properties [1]

Sodium nitrate [7631-99-4], Chile saltpeter, Chilean nitrate, $NaNO_3$, M_r 85.00, has an enthalpy of formation ΔH = –466.8 kJ/mol [2], an enthalpy of fusion ΔH = + 15.7 kJ/mol [3] and *m p* 306.8 °C [3]. For pressure dependence of the melting point see [4]. At 25 °C, anhydrous sodium nitrate forms colorless trigonal crystals of space group D_{3d}^{6}; ϱ_{298} = 2.261 g/cm^3 [3]; $C_{p,\,298}$ = 93.1 J mol^{-1} K^{-1} [2]; refractive index at 589 nm n_{ω} = 1.587, n_{ϵ} = 1.336 [3]. This modification forms trigonal crystals of space group D_{3d}^{5} at a transition point of ca. 275 °C.

Sodium nitrate does not form hydrated solid phases (Fig. 1). The salt is hygroscopic and readily dissolves in water; at 25 °C, 92.1 g dissolves in 100 g of water [3]; enthalpy of solution at infinite dilution ΔH_{298} = + 20.5 kJ/mol [3]. Sodium nitrate is soluble in liquid ammonia and forms $NaNO_3 \cdot 4NH_3$ below –42 °C. The solubility of sodium nitrate in anhydrous methanol is 2.8 wt % at 25 °C [5].

Figure 1. Properties of a saturated solution of sodium nitrate in water

a) Density; b) Content of sodium nitrate; c) Vapor pressure *bp* = boiling point of saturated solution containing 68.5 wt % sodium nitrate at 101.3 kPa and 119 °C; E = cryohydric point: –17.5 ± 0.5 °C, 38.0 % sodium nitrate.

Sodium nitrate is an oxidant and releases oxygen on heating:

$$NaNO_3 \rightleftharpoons NaNO_2 + 1/2\,O_2\ \Delta H_{298} = +109\,\mathrm{kJ/mol} \qquad (1.1)$$

Molten sodium nitrate remains stable in air up to 500 °C; reaction (1.1) reaches equilibrium with the evolution of oxygen between 600 and 750 °C [6]. The product (sodium nitrite) decomposes (see Section Properties). Alkali nitrates contain small amounts of nitrites at temperatures as low as 300 °C [7]. In aqueous solution, alkali nitrates have little oxidizing power; they are reduced to ammonia by nascent hydrogen.

1.2. Occurrence

Deposits of sodium nitrate (the mineral nitratine) occur chiefly in arid regions such as Peru, Mexico, Egypt, and South Africa. The only commercial deposits are, however, in Chile. The origin of these deposits has not been determined conclusively. A number of theories have been proposed since the early 1960s [8-10].

The Chilean deposits lie between latitudes 19 ° and 26 ° at ca. 800 – 1600 m above sea level. The uppermost bed is 20 – 40 cm thick and consists of unconsolidated weathering products containing only a little salt (“chuca”). The next bed, up to 3 m thick, is called “costra”; it is usually a coarse breccia cemented with clay and salts of the saltpeter deposits. The “caliche” or salt bed proper lies beneath and has a thickness of 0.5 – 5.0 m. It is also brecciated and contains various salts (Table 1) and widely varying amounts of clay, sand, and gravel.

Table 1. Analyses of caliche samples (composition in wt %)

Salt	1	2	3	4	5
$NaNO_3$	34.2	34.4	43.3	28.5	53.5
KNO_3	1.6				17.3
Na_2SO_4	8.4	1.6	25.3	5.4	1.9
$CaSO_4$	6.3	1.6	30.9	2.7	0.5
$MgSO_4$	2.0	5.4		3.4	1.4
NaCl	32.0	4.0		17.2	21.3

In addition to nitratine ($NaNO_3$) and generally a little niter (KNO_3), the rock often contains a wide variety of components: halite (NaCl), gypsum ($CaSO_4 \cdot 2H_2O$), anhydrite ($CaSO_4$), bloedite ($Na_2SO_4 \cdot MgSO_4 \cdot 4H_2O$), glauberite ($Na_2SO_4 \cdot CaSO_4$), polyhalite ($K_2SO_4 \cdot MgSO_4 \cdot 2CaSO_4 \cdot 2H_2O$), and darapskite ($NaNO_3 \cdot Na_2SO_4 \cdot H_2O$). In addition to the salts listed in Table 1, borates, iodates, other iodine compounds, and perchlorates may be present in amounts up to a few tenths of a percent.

Reserves may well support several more centuries of working. In Chile alone, reserves of commercial caliche containing 7 wt % sodium nitrate are estimated at 2.5×10^9 t. Reserves of lower quality are about ten times greater [11].

1.3. Production

1.3.1. *Chile Saltpeter*

The winning of sodium nitrate from caliche is very complicated. The raw material contains only 7 – 40 wt % sodium nitrate (corresponding to 2 – 7 % N) and requires multistage processing to achieve an acceptable yield. The saltpeter industry in Chile produces ca. 600 000 t of sodium nitrate, 50 000 t of sodium sulfate, and more than 3000 t of iodine yearly [12]; it is one of the world's leading producers of iodine (⟶ , ⟶ Iodine and Iodine Compounds – Economic Aspects).

As early as 1810, low yields of impure saltpeter were produced by small boileries in Chile. The first improvement was the *Shanks hot-leaching process*, introduced in 1876 [13], [14]. Caliche with a minimum sodium nitrate content of 13 wt % was extracted with mother liquor at ca. 110 °C; after crystallization of sodium chloride at < 5 °C, the product was obtained by crystallization at 22 °C. The yield was 65 – 80 %, and the energy cost was high. The 200 or so plants employing the Shanks process ranged in capacity from 10 000 to 100 000 t/a of sodium nitrate. High energy costs made the Shanks process uncompetitive with synthetic saltpeter after World War I.

The *Guggenheim low-temperature leaching process* was developed in 1923 [8], [15]. By the beginning of the 1930s, two Guggenheim plants with sodium nitrate capacities of 500 000 and 600 000 t/a had been built. The Guggenheim process features relatively low leaching temperatures (40 – 45 °C), 90 % yields, low energy consumption due to good heat utilization, rational methods of caliche mining, and very large plant units. The process can economically handle caliche containing as little as 7 wt % sodium nitrate. Old spoil heaps of spent earth can be processed along with residues from leaching the coarse caliche fraction containing > 7 wt % sodium nitrate.

The isolation of sodium nitrate is based on differences between the solubility curves of the salts contained in the caliche. For example, the solubility of sodium nitrate is four times greater than the solubility of sodium chloride in water at 45 °C (Fig. 2). Operating conditions must be avoided under which insoluble or sparingly soluble double salts containing sodium nitrate are stable. For example, if the Mg^{2+} and Ca^{2+} concentration in the recycle liquor is sufficiently high, darapskite ($NaNO_3 \cdot Na_2SO_4 \cdot H_2O$) forms the insoluble “protective compounds” blödite ($Na_2SO_4 \cdot MgSO_4 \cdot 4\,H_2O$) and glauberite ($Na_2SO_4 \cdot CaSO_4$). Darapskite is a sparingly soluble component that accounts for 30 % of the sodium nitrate in caliche and is stable below 55 °C.

Figure 2. Solubility curves of sodium nitrate and sodium chloride in a saturated aqueous solution containing solid sodium nitrate and sodium chloride [16]

The production of Chile saltpeter from caliche is summarized in Figure 3. The warm (40 – 45 °C) mother liquor recycled to leaching contains ca. 330 g/L of sodium nitrate. The leaching process is performed in a series of vats, each having a capacity of ca. 1000 t of crushed ore. The underflow of each vat is heated before passing to the next one since the dissolution of sodium nitrate is endothermic. Sodium nitrate therefore dissolves preferentially. The product solution obtained after leaching contains 450 g/L of sodium nitrate and is cooled to 5 – 10 °C in heat exchangers and with ammonia refrigerating equipment. The mother liquor obtained after centrifugation of crystallized sodium nitrate is heated to 40 – 45 °C with heat from the condensers in the ammonia chilling loop and then with cooling water from the diesel engines used to generate electric power. Crystalline sodium nitrate obtained after centrifugation contains 3.0 – 3.5 % moisture; it is generally melted at ca. 340 °C and

prilled. The granulated product contains only about 1 % sodium chloride. Table 2 gives a detailed product analysis [17]. Large modern plants also produce coarse crystals of Chile saltpeter, which do not require further processing by melting.

Table 2. Analysis of saltpeter products

Component	Granulated sodium nitrate, * wt %	Granulated potassium nitrate,* wt %	Synthetic saltpeter, wt %
$NaNO_3$	98.32	67.37	99.70
KNO_3		30.36	0.06
NaCl	0.67	0.97	0.09
$Na_2B_4O_7$	0.24	0.23	
$NaIO_3$	0.03	0.03	
Moisture	0.17	0.21	0.10
Undetermined	0.57	0.83	0.05

* From Chile saltpeter [17].

Figure 3. Guggenheim process for the production of Chile saltpeter

To recover more than 80 % of the sodium nitrate present in caliche, the “spent earth” containing 1.0 – 1.5 wt % sodium nitrate must be leached with water. The resulting dilute liquor is either used for leaching fine caliche (Fig. 3) or placed in large open pans and evaporated by the sun and the hot dry winds of the salt desert; precipitated crystals are removed periodically. Greater utilization of solar energy in the future will allow economical processing of caliche containing as little as 4 % sodium nitrate.

Byproducts. Iodine recovery from the mother liquor begins when the sodium iodate content reaches 6 – 9 g/L. The enriched solution is treated with sodium hydrogen sulfite to precipitate free iodine:

$$2\,NaIO_3 + 5\,NaHSO_3 \rightarrow I_2 + 3\,NaHSO_4 + 2\,Na_2SO_4 + H_2O \quad (1.2)$$

Iodine is separated by filtration and purified by sublimation. The side stream after iodine recovery is returned to the circulating mother liquor.

The recovery of Chile niter (KNO_3) as a byproduct is profitable if the caliche contains > 2 – 3 wt % potassium nitrate. This product also accumulates in the mother liquor. To reduce processing costs, the product is refined to a potassium nitrate content of only 30 % (Table 2).

1.3.2. *Synthetic Sodium Nitrate*

The most important method for producing synthetic sodium nitrate is the reaction of tail gases from nitric acid plants with sodium hydroxide or sodium carbonate solution. This method is, however, intended for tail-gas clean-up (removal of nitrogen oxides) rather than for nitrate and nitrite production.

Tail-gas absorption initially yields some sodium nitrate and larger amounts of sodium nitrite. The reactions that produce nitrite alone

$$2\,NaOH + NO_2 + NO \rightarrow 2\,NaNO_2 + H_2O \quad (1.3)$$

$$Na_2CO_3 + NO_2 + NO \rightarrow 2\,NaNO_2 + CO_2 \quad (1.4)$$

proceed faster than the reactions that produce both nitrite and nitrate.

$$2\,NaOH + 2\,NO_2 \rightarrow NaNO_3 + NaNO_2 + H_2O \quad (1.5)$$

$$Na_2CO_3 + 2\,NO_2 \rightarrow NaNO_3 + NaNO_2 + CO_2 \quad (1.6)$$

The countercurrent absorption process takes place in 18–8 stainless steel columns connected in series. In sodium carbonate absorption, the columns are packed with ceramic rings; iron rings are used for sodium hydroxide absorption.

Fresh alkaline solution is circulated into the last column. The liquor is forwarded batchwise to successive columns and finally withdrawn with a content of ca. 500 g/L of sodium nitrate and sodium nitrite. The product liquor contains both nitrate and nitrite, even if nitrite removal is employed (see Chap. Sodium Nitrite). Nitrite is decomposed by inversion with nitric acid at 50 °C in a column made of 18–8 steel prior to nitrate recovery:

$$3\,NaNO_2 + 2\,HNO_3 \rightarrow 3\,NaNO_3 + 2\,NO + H_2O \qquad (1.7)$$

The highly concentrated nitrogen monoxide can be used to synthesize other compounds (e.g., hydroxylamine) or can be returned to the nitric acid plant.

The residual nitrogen monoxide is stripped from the inverted solution with steam or air at ca. 100 °C. The solution is then neutralized with sodium carbonate or sodium hydroxide, passed through a precoat filter, and concentrated batchwise in multistage iron evaporators. The first stage is operated at 100 – 120 °C (p = 120 – 150 kPa in the vapor space). The resulting solution should not crystallize and should still dissolve any salt deposits formed in the second stage. The second stage is operated under vacuum (p = 10 – 20 kPa) at 65 – 75 °C; the product is concentrated to form a slurry containing ca. 20 % precipitated sodium nitrate. The crystals are separated in a centrifuge without cooling. Depending on the quality required, they are washed more or less intensively with cold water. Sodium nitrate from the centrifuge has a moisture content of 2 – 3 wt % and is dried to ca. 0.1 wt % moisture in drums heated with flue gas. The product is dried, cooled, and stored in bins.

The mother liquor from the centrifuge is recycled to the first evaporator stage along with the wash water. Discharge of the liquor is only necessary if the alkali used contains more chloride than permitted in sodium nitrate by quality standards. Accordingly, the process generally does not produce any wastewater.

1.4. Product Forms, Storage, and Transportation

Chile saltpeter is marketed as both a “granular” product (mainly used as a fertilizer) and a coarse crystalline product. Technical-grade synthetic sodium nitrate is a fine, crystalline white powder with a bulk density of about 1.36 kg/L. It is sold as an untreated product and also as a free-flowing product containing up to 0.1 % alkyl aryl sulfonate as an anticaking agent [18]. Table 2 presents analyses of sodium nitrate.

Sodium nitrate can be transported in bulk form. The technical grade, especially the untreated product, is generally shipped in polyethylene bags. As an oxidizing agent, sodium nitrate must not come in contact with readily oxidizable products during transport and storage.

1.5. Uses

Inorganic nitrates and nitrites overlap in their areas of application. Mixtures of the compounds are sometimes employed. More than half of the sodium nitrate produced worldwide (including Chile saltpeter) is used as a fertilizer for crops such as cotton, tobacco, and vegetables. In contrast to other nitrogen fertilizers, sodium nitrate does not overacidify the soil. In Europe and the United States, sodium nitrate is of minor importance compared to other fertilizers.

The major industrial use of sodium nitrate is in the explosives industry. It is employed along with ammonium nitrate in the production of water-containing slurry and gel explosives, whose consistency is stabilized with rubber additives. Sodium nitrate, like potassium nitrate, is added to ammonium nitrate melts (see Section Uses). Sodium nitrate is also used in pyrotechnics, for example, in flare mixtures.

Large amounts of sodium nitrate are used in the glass and enamel industry as a refining agent for removing air bubbles from melts.

In metallurgy, molten salt mixtures containing sodium nitrate are employed as heat-transfer baths for quench hardening and tempering of steel, light alloys, and copper alloys. For the range 260 – 550 °C, $NaNO_3$ – KNO_3 melts are used; melts containing ca. 45 % sodium nitrite along with potassium nitrate and sodium nitrate can be used from 150 to 300 °C [19]. The heat of fusion of the salt mixture can be utilized to keep the temperature constant; the solidification point of the ternary system KNO_3 – $NaNO_3$ – $NaNO_2$ can be adjusted precisely by altering the proportion of components. Metal parts with oxide scales can be pretreated by briefly dipping them in molten $NaNO_3$ – NaOH so that they can be electrically descaled in a sodium sulfate solution without the use of acid (more environmentally friendly); similar methods employ potassium nitrate.

Molten mixtures of sodium nitrate, other alkali nitrates, and nitrites function as heat-transfer and heat-storage media in solar technology. The maximum temperature for this application is ca. 600 °C. The thermophysical properties of such melts are described in [20-23].

Mixtures of sodium nitrate and borax also serve as an auxiliary in soldering and welding. Sodium nitrate is recommended as a corrosion-inhibiting additive in antifreezes and cooling brines. In the regeneration of spent sulfuric acid by distillation in cast-iron vessels, passivation with sodium nitrate is used to prevent corrosion.

Sodium nitrate is used to promote combustion; it is added to activated carbon when sulfur dioxide is oxidized to sulfur trioxide in exhaust-gas combustion devices and is also used to improve the combustibility of tobacco. Cleaning agents for plugged drain pipes are made from sodium nitrate, aluminum filings, and an alkali; hydrogen produced by the action of water is oxidized by sodium nitrate, and this reaction provides the heat needed for effective cleaning. Molten sodium nitrate serves as a reaction medium, for example, in the electrolytic production of chromium dioxide for magnetic tape. A melt of sodium nitrate and potassium nitrate provides a suitable medium for the thermal decomposition of dissolved ammonium nitrate to dinitrogen monoxide. The same melt can be used for the conversion of urea to cyanuric acid in a method devised by Stamicarbon. Pickling salt contains sodium nitrate.

Other applications of sodium nitrate include the production of dyes, pharmaceuticals, charcoal briquetts, and other nitrates.

1.6. Economic Aspects

The output of Chile saltpeter has decreased continually since the late 1920s (Table 3). Despite competition from synthetic sodium nitrate, output seems to have reached a stable level. In Chile, production capacity increased in 1984 [24], and another plant is planned [25]. The cost of producing Chile saltpeter is far less sensitive to rising energy prices than that of synthetic sodium nitrate, which requires ammonia and caustic soda as feedstocks. Most Chile saltpeter is exported; the most important consumers are Western Europe (120 000 t/a), especially Spain and The Netherlands, and the United States (100 000 t/a) [17].

Table 3. Production of Chile saltpeter (10^3 t)

Year	Production	Year	Production
1830	1	1940	1380
1850	30	1950	1660
1880	220	1960	930
1900	1650	1970	700
1910	2470	1975	800
1920	2530	1979	650
1928	3160	1984	710
1933	530	1987	590

Few production figures are available for synthetic sodium nitrate. Sodium nitrate has not been manufactured in the United States since 1988. Further stagnation of sodium nitrate production is expected in the near future. This forecast could change if solar energy development is stepped up [26].

[Top of Page]

2. Potassium Nitrate

Potassium nitrate was manufactured in China with the aid of bacteria as early as the Middle Ages. Up to the beginning of the 20th century, its only important use was in the production of gunpowder.

2.1. Properties [27]

Potassium nitrate [7757-79-1], saltpeter, KNO_3, M_r 101.10, has an enthalpy of formation ΔH_{298} = –492.8 kJ/mol [2], an enthalpy of fusion ΔH = +11.9 kJ/mol [3], and *mp* 334 °C; for pressure dependence of the melting point, see [4]. At 25 °C, anhydrous potassium nitrate forms colorless rhombic crystals of space group $D_2^{16}{}_h$; ϱ_{298} = 2.109 g/cm^3; $C_{p,\,298}$ = 96.36 J mol^{-1} K^{-1} [2]; refractive index at 589 nm n_α = 1.335, n_β = 1.5056, n_γ = 1.5064 [2]. This modification forms rhombic crystals of space group D_{3d}^5 at a transition point of ca. 127.7 °C (enthalpy of formation ΔH = +5.1 kJ/mol) [28], [29]. High-pressure allotropes account for the caking tendency of potassium nitrate [30].

Potassium nitrate does not form solid phases containing water (Fig. 4). Its enthalpy of solution in water at infinite dilution is ΔH_{298} = +34.9 kJ/mol [3]. Potassium nitrate is soluble in liquid ammonia; no ammoniates are known. The solubility of potassium nitrate in anhydrous methanol at 25 °C is 0.34 wt % [5].

Figure 4. Properties of a saturated solution of potassium nitrate in water

a) Density; b) Content of potassium nitrate; c) Vapor pressure

bp = boiling point of saturated solution containing 77.0 wt % potassium nitrate at 101.3 kPa and 115.6 °C; E = cryohydric point: –2.85 °C, 9.66 % potassium nitrate.

Like sodium nitrate, potassium nitrate liberates oxygen on heating. The endothermic reaction

$$KNO_3 \rightleftharpoons KNO_2 + 1/2\,O_2 \quad \Delta H_{298} = +124\,\mathrm{kJ/mol} \tag{2.1}$$

is reversible. In contact with air, pure molten potassium nitrate is stable up to about 530 °C; reaction (2.1) comes to equilibrium between 650 and 750 °C. Above 750 °C, the nitrite product decomposes with the formation of nitrogen oxides [6]. The KNO_3 – $NaNO_3$ system forms a eutectic with 45 % sodium nitrate, *mp* ca. 218 °C. Solid solutions exist above 175 °C with no miscibility gap; at room temperature the system has a miscibility gap from 0.5 to 99.9 wt % sodium nitrate. The composition of the aqueous solution saturated with both salts is described in [31].

2.2. Occurrence

Potassium nitrate (in the form of the mineral niter) occurs as efflorescences on soils. Deposits in China and the East Indies were economically important; in the first half of the 19th century, more than 10 000 t/a of potassium nitrate were produced by

leaching such soils (current annual production is still several thousand tonnes). Before the large-scale manufacture of converted saltpeter began, East Indian saltpeter enjoyed a virtual monopoly.

Potassium nitrate is present in tobacco plants, from which it can be extracted with water and recovered to diminish nitrogen oxide evolution during smoking.

2.3. Production

For older processes, see [14], [27].

2.3.1. *Bacterial Production of Saltpeter*

Bacterial production of potassium nitrate was employed from the 17th to the 19th century in Europe. This was necessary to avoid having to import this raw material, which was indispensable for military purposes during wartime. Nitrogen-rich organic wastes, especially animal feces and urine, were placed in loose, air-permeable piles of earth together with lime and potash; the nitrogen compounds were converted to nitrates by bacterial nitrification. After several years, the mass was leached with water. Potash was added to the crude liquor to convert calcium and magnesium nitrates to potassium nitrate and sparingly soluble calcium and magnesium carbonates. The filtered liquor was evaporated to obtain saltpeter, which was purified by recrystallization.

2.3.2. *Converted Saltpeter*

From the mid-19th century until the 1950s, the conversion of Chile saltpeter with potassium chloride was the most important potassium nitrate production process (Fig. 5). Potassium chloride was supplied in large quantities after 1860 by the German potash industry.

Figure 5. Conversion of sodium nitrate to potassium nitrate

$$NaNO_3 + KCl \rightleftharpoons KNO_3 + NaCl \tag{2.2}$$

The process is based on the slight increase in solubility of sodium chloride with temperature. The mother liquor from potassium nitrate crystallization in the preceding cycle (point C in Fig. 6) is heated and reacted with stoichiometric quantities of sodium nitrate and potassium chloride. Impure starting materials are generally used in this step. The reaction mixture (point A, Fig. 6) is concentrated at 100 °C with the addition of sodium carbonate; sodium chloride and impurities (e.g., $MgCO_3$) precipitate and are filtered out. The filtrate (point B, Fig. 6) is again diluted with the evaporation condensate (to prevent sodium salts from precipitating on cooling), clarified, cooled to 5 °C to precipitate potassium nitrate, and centrifuged. The mother liquor (point C, Fig. 6) is recycled. The potassium nitrate product is recrystallized for technical purposes. Because of high energy costs and other factors, the conversion process can no longer compete with the processes described in Sections Potassium Nitrate from Calcium Nitrate, Potassium Nitrate from Ammonium Nitrate, Potassium Nitrate from Potassium Chloride and Nitric Acid; nevertheless, older plants continue to use it. Physical and chemical fundamentals are described in [32-35]; process design may be found in [36], [37].

Figure 6. The $NaNO_3$ – KNO_3 – KCl – NaCl – H_2O system

Jänecke's method [34] is used to plot the relative content of cations and anions in percent equivalents in the salt mixture corresponding to the saturated solution. Absolute concentrations or quantities of water are not shown. Values for 5 °C are according to [32], for 100 °C according to [33].

The lines labeled 5 and 100 °C represent the boundaries of fields in each of which one of the four salts occurs as the solid phase in the saturated solution. In the shaded region, sodium chloride precipitates from the saturated solution at 100 °C but potassium nitrate precipitates at 5 °C. (See text for explanation of the working triangle ABC.)

2.3.3. *Potassium Nitrate from Calcium Nitrate*

A number of processes have been developed for obtaining potassium nitrate from calcium nitrate, which is a byproduct of other processes (e.g., digestion of rock phosphate with nitric acid).

With potassium sulfate as a starting product, the reaction

$$Ca(NO_3)_2 + K_2SO_4 + 2\,H_2O \rightarrow 2\,KNO_3 + CaSO_4 \cdot 2\,H_2O \tag{2.3}$$

yields sparingly soluble gypsum, which is easily separated. This is the basis for the relatively simple Victor process [38], which was employed after 1951 in Germany for several decades to manufacture potassium nitrate [39]. Other methods employ potassium chloride as raw material but have no industrial importance [39].

In another proposed process, limestone is first reacted with nitric acid to form calcium nitrate. Potassium sulfate is then added to the resulting liquor at ca. 100 °C. The gypsum formed is removed and the reaction mixture is cooled. Potassium nitrate crystals are isolated with a purity of 99.5 %, and the mother liquor is recycled to the beginning of the process [40].

A process based on the use of calcium nitrate and ion exchangers has also been proposed [41].

2.3.4. *Potassium Nitrate from Ammonium Nitrate*

Potassium nitrate is made from ammonium nitrate (available in high purity) and potassium chloride by double decomposition in aqueous solution:

$$NH_4NO_3 + KCl \rightarrow KNO_3 + NH_4Cl \tag{2.4}$$

The ammonium chloride byproduct is easily separated.

The solubility relationships (Fig. 7) in the system of reciprocal salt pairs described in reaction (2.4) [42] lead to a simple reaction design (Fig. 8) [43]. The starting reagents are added in alternate stages. Ammonium chloride precipitates at a higher temperature and from a higher concentration than potassium nitrate. Evaporation is therefore necessary prior to ammonium chloride crystallization, the condensate being recycled before potassium nitrate crystallization. Because the salt solution is aggressive, molybdenum-alloyed carbon steel is used for process equipment. Fertilizer-grade product containing 95 wt % potassium nitrate and 5 wt % ammonium nitrate is manufactured by this process [24], [44].

Figure 7. The NH_4NO_3 – KNO_3 – KCl – NH_4Cl – H_2O system (see Fig. 6 for the method of plotting)

In the shaded region, ammonium chloride precipitates from the saturated solution at 60 °C but potassium nitrate precipitates at 0 °C. Absolute concentrations are not shown (see [41]).

Figure 8. Potassium nitrate production from ammonium nitrate

2.3.5. *Potassium Nitrate from Potassium Chloride and Nitric Acid*

Production without Chlorine Formation. In an aqueous medium containing 50 % nitric acid, the reaction

$$HNO_3 + KCl \rightleftharpoons KNO_3 + HCl \tag{2.5}$$

proceeds without oxidation of chloride ion to chlorine and/or nitrosyl chloride only if the temperature is below 40 °C (or below 70 °C at 40 % HNO_3). A number of process design options are available: removing hydrogen chloride by absorption, decreasing potassium nitrate solubility by the addition of alcohol, or using cation exchangers. Only the Israel Mining Industry (IMI) process has been introduced on a large scale (Fig. 9) [45]. Solid potassium chloride is reacted with nitric acid at 5 – 10 ° C (c) in the presence of an organic solvent (*n*-butanol or isopentanol). The solvent extracts the hydrogen chloride, and potassium nitrate is precipitated quantitatively from the aqueous phase. The advantage of the low digestion temperature is that hydrogen chloride is extracted from the organic solvent in preference to nitric acid; furthermore, the aqueous solution contains less potassium nitrate. The three phases present (potassium nitrate, aqueous phase, organic phase) are then separated. The potassium nitrate is centrifuged and washed with water (e). The aqueous phase is returned to the reactors (c). The purity of the product (> 95 %) [46] is sufficient for use as fertilizer; recrystallization is necessary for the technical grade. Hydrogen chloride is separated as a 22 % aqueous solution from the alcohol (which is not miscible with water in all proportions) by countercurrent extraction with water in three mixer – settler units (f). After extraction, the alcohol, which contains nitric acid, is returned to the conversion reactor. Separation of hydrochloric acid from the solvent has been improved by use of a different solvent that extracts nitric acid preferentially and extracts virtually no hydrochloric acid [47]. Haifa Chemicals uses tributyl phosphate for this purpose. Another proposal for improving the process is to replace the alcohol by an organic acid and an amine [48]. Rigid poly(vinyl chloride) and titanium are used as construction materials, with graphite for distillation equipment. A substantial portion of investment is for solvent conditioning.

Figure 9. Simplified flow sheet of the IMI process (based on literature data)

a) Potassium chloride supply; b) Cooler; c) Reactor; d) Decanter; e) Centrifuge; f) Extractor (I = mixer, II = separator); g) Multistage evaporator (details not published)

Dashed lines indicate streams containing mainly isopentanol.

This process is employed in two potassium nitrate plants in Haifa. Potassium nitrate output in 1987 was 250 000 t, of which ca. 30 000 t was of technical purity and the remainder fertilizer grade [49]. The hydrochloric acid byproduct is utilized for the digestion of rock phosphate.

Production with Chlorine Formation. The South West Potash Corporation (SWP) process is employed on a large scale for

the production of potassium nitrate and chlorine [44], [50]. The most important steps follow (Fig. 10) [14]:

Figure 10. South West Potash Corporation process

1. Potassium chloride is reacted with 65 % nitric acid in an autoclave at 75 °C and ca. 200 kPa to yield potassium nitrate, chlorine, and nitrosyl chloride.

$$4\,HNO_3 + 3\,KCl \rightarrow 3\,KNO_3 + Cl_2 + NOCl + 2\,H_2O \quad (2.6)$$

2. Nitrosyl chloride is oxidized with 80 % nitric acid to yield chlorine and nitrogen dioxide.

$$NOCl + 2\,HNO_3 \rightarrow 1/2\,Cl_2 + 3\,NO_2 + H_2O \quad (2.7)$$

3. Nitrogen dioxide is oxidized with oxygen and absorbed in water to yield 65 % nitric acid, which is recycled to the potassium chloride conversion step.

$$4\,NO_2 + O_2 + 2\,H_2O \rightarrow 4\,HNO_3 \quad (2.8)$$

(Alternatively, nitrogen dioxide can be withdrawn as end product.)

4. The solution of potassium nitrate and nitric acid is concentrated to > 80 % nitric acid by crystallization of potassium nitrate in a vacuum crystallizer. Nitric acid can be obtained in 75 % or 85 % concentration because the azeotropic concentration in the HNO_3 – H_2O system at 80 kPa increases to 82 % nitric acid if the liquid phase contains 40 % potassium nitrate and to 87 % nitric acid at 50 % potassium nitrate [51].
5. The potassium nitrate is centrifuged, dried, melted at 340 – 350 °C, and prilled.

Intense corrosion dictates the use of titanium reactors with acid-resistant linings, whereas tower internals are made of glass or Teflon.

At present, Cedar Chemical Corp. (Trans-Resources) has an annual capacity of 100 000 – 120 000 t of potassium nitrate in an SWP plant at Vicksburg, Mississippi; ca. 20 000 t/a of the output is technical grade. Chlorine, dinitrogen tetroxide, and 65 % nitric acid are obtained as byproducts.

2.4. Product Forms, Storage, and Transportation

All technical-grade and most fertilizer-grade potassium nitrate is sold as a fine crystalline product with a bulk density of 1.1 kg/L. Technical grades may be untreated or treated with fatty amines or stearates to prevent caking [18]. Fertilizer-grade potassium nitrate is also sold as prills (bulk density 1.3 kg/L, obtained by atomizing a melt at 340 °C), because prills have better storage qualities and are easier to apply as fertilizer. Table 4 gives the analyses of typical grades. As a rule, the technical product is shipped in plastic or multi-ply paper bags. As an oxidant, potassium nitrate must not be stored or transported with easily oxidized products.

Table 4. Composition (wt %) of potassium nitrate

Component	Technical grade		Fertilizer grade	
	Requirements for black powder *	Sample	Product I	Product II
KNO_3	min. 99.0	99.8	95.0	96.5
Cl^-	max. 0.03	0.015	0.2	1.8
NO_2^-	not specified		0.002	0.2
SO_4^{2-}	not specified	0.02	3.4	0.05
Na^+	max. 0.1	0.02	0.2	0.7
Ca^{2+} and Mg^{2+}	max. 0.07	0.03	1.0	0.1
Heavy metals	max. 0.1		0.02	0.02
Insolubles	max. 0.1	0.05	0.05	0.2
H_2O	max. 0.25	0.06	0.1	0.1

* Not all requirements are shown.

2.5. Uses

About 75 % of potassium nitrate is manufactured with a purity of only 90 % for use as a nonhygroscopic fertilizer. The absence of chlorine is advantageous for growers of tobacco, citrus fruits, and vegetables (especially for hothouse crops). Potassium nitrate can also be used in the production of clear liquid fertilizers and is an important constituent of multinutrient fertilizers.

Almost half of the technical-grade product is employed in metallurgy, mainly in heat-transfer baths in mixtures with other nitrates and nitrites (see Section Uses). Potassium nitrate is also a component of soldering fluxes and welding electrodes. Large amounts are used in the glass, enamel, and ceramics industries. Glass devices and optical lenses can be improved by techniques based on Na^+ – K^+ ion exchange (treatment of sodium-containing glasses in molten KNO_3).

About 10 – 20 % of technical-grade potassium nitrate is consumed in the manufacture of explosives and pyrotechnics. Along with sodium nitrate and ammonium nitrate, potassium nitrate is an oxygen supplier in safety explosives. Because of its low hygroscopicity, potassium nitrate remains an important raw material for the production of matches and primer cords, as well as primer compositions with controlled burning rate for local heating. Another important use in the explosives industry is the addition of 2 – 10 % potassium nitrate to ammonium nitrate to lower the melting point, which facilitates prilling and improves the stability of the resulting granules.

Small amounts of potassium nitrate are employed in food preservation, cheese processing, and for improving the quality of tobacco.

Because of its oxidizing properties, potassium nitrate can be used for desooting in combustion processes. It is also recommended as an agent for controlling noxious odors during the application of sewage sludge or manure (at the same time, it improves the fertilizing action of the waste).

Potassium nitrate has been proposed as an oxidizing component in an acid-based gas generator system for the rapid inflation of air bags used to prevent injuries in motor vehicle accidents.

Potassium nitrate is also employed as an oxidant in chemical syntheses (e.g., alizarin synthesis).

2.6. Economic Aspects

Except for the small output from deposits still worked in India and the production of Chile saltpeter (which contains only 20 – 30 % KNO_3, see Section Chile Saltpeter), the only source of potassium nitrate for more than 100 years has been synthetic production. Although use of the technical-grade product can be expanded only slightly, a variety of processes have been developed to reduce the cost of manufacturing impure saltpeter and to increase its use as a fertilizer.

World production capacity in 1987 for synthetic potassium nitrate is about 425 000 t/a, 75 % of which is fertilizer grade and only 25 % technical grade (see Table 5). The largest producer is Trans-Resources with 340 000 t/a (Cedar Chemical and Haifa Chemicals, Israel) [52]. Israel is the largest exporter; its most important customers are the United States, Western Europe, and Latin America. By 1992, Haifa Chemicals will boost its capacity to 300 000 t/a [53]. The annual output of Chile saltpeter is 60 000 – 75 000 t of potassium nitrate. Soquimich, the sole manufacturer in Chile, is the third largest potassium nitrate producer in the world [54].

Table 5. Potassium nitrate capacities in 1987 (10^3 t)

Country	Fertilizer grade	Technical grade
Israel	250	30
United States	80	20
FRG	0	30
Other West European countries	20	20
Eastern bloc	*	30
India	*	*
Chile (natural saltpeter)	60 – 75	0

* Capacity unknown.

[Top of Page]

3. Calcium Nitrate

3.1. Properties [55]

Calcium nitrate [10124-37-5], $Ca(NO_3)_2$, M_r 164.09, has an enthalpy of formation of ΔH_{298} = –937.4 kJ/mol [2]. Anhydrous calcium nitrate crystallizes in the cubic system, space group T^6_h; ϱ_{298} = 2.504 g/cm^3 [3]; $C_{p,\ 298}$ = 149.5 J mol^{-1} K^{-1} [2]; refractive index n = 1.595 at 589 nm; $m\,p$ 561 °C (incipient decomposition).

Anhydrous calcium nitrate is highly hygroscopic and readily soluble in water when heated (enthalpy of solution ΔH_{298} = –18.7 kJ/mol at infinite dilution [56]); see also Figure 11 and Table 6. In addition to the anhydrous salt, three hydrates are known [57], [58]. The tetrahydrate [13477-34-4], $Ca(NO_3)_2 \cdot 4H_2O$, is the most important industrially: enthalpy of formation ΔH_{298} =+2130 kJ/mol; monoclinic crystals of space group C^5_{2h}; ϱ_{298} = 1.896 g/cm^3; refractive index at 589 nm n_α = 1.465, n_β = 1.498, n_γ = 1.504. The tetrahydrate dissolves in water with strong cooling (enthalpy of solution ΔH_{292} = + 32.7 kJ/mol at infinite dilution).

Table 6. Data for the system $Ca(NO_3)_2 - H_2O$ (see also Fig. 11)

Transition point and temperature, °C		Content of $Ca(NO_3)_2$, wt %	Range	Stable hydrate formula	*mp*, °C
E *	–28.7	42.9			
			E – A	$Ca(NO_3)_2 \cdot 4H_2O$	42.7
A	+42.6	70.8			
			A – B	$Ca(NO_3)_2 \cdot 3H_2O$	51.1
B	+50.6	77.2			
			B – C	$Ca(NO_3)_2 \cdot 2H_2O$	
C	+51.6	78.1			
			above C	$Ca(NO_3)_2$	561
bp **	+151	79.0			

Water vapor pressure over saturated solution with solid $Ca(NO_3)_2 \cdot 4H_2O$

Pressure, kPa	0.36	0.69	1.25	1.99	2.63

* E = cryohydric point.
** Boiling point (101.3 kPa) of the saturated solution.

Figure 11. Properties of a saturated solution of calcium nitrate in water (see Table 6 for explanations)

a) Density; b) Content of calcium nitrate; c) Vapor pressure

Calcium nitrate dissolves readily in liquid ammonia, methanol, and ethanol. A number of ammoniates are known.

Thermal decomposition of calcium nitrate

$$Ca(NO_3)_2 \rightarrow CaO + 2\,NO_2 + 1/2\,O_2\ \Delta H = +369\ \mathrm{kJ/mol} \tag{3.1}$$

begins at 500 °C [6]. For the reaction mechanism, see [59].

Double Salts. Several weakly hygroscopic double salts are formed with ammonium nitrate [55]. The double salt $NH_4NO_3 \cdot 5Ca(NO_3)_2 \cdot 10H_2O$ has a high melting point (102 °C) and is important in the production of granular calcium nitrate. The double salt with urea, $Ca(NO_3)_2 \cdot 4CO(NH_2)_2$, is nonhygroscopic and can be employed as a fertilizer. The system $Ca(NO_3)_2 - KNO_3 - H_2O$ includes the phase $Ca(NO_3)_2 \cdot 4KNO_3$ [60].

3.2. Occurrence

Only small amounts of $Ca(NO_3)_2 \cdot 4H_2O$ occur (nitrocalcite) as efflorescences in limestone caves, for example, in Kentucky.

3.3. Production

Calcium nitrate became the first synthetic nitrogen fertilizer under the name Norge saltpeter. It was made by dissolving limestone in nitric acid and neutralizing the resulting liquor with powdered limestone or lime. This process is still in use, but ammonia is now employed for neutralization.

Calcium nitrate is also an important byproduct of nitric acid digestion of rock phosphates by the Odda process (

⟶ Phosphate Fertilizers). It is either used directly for fertilizer production or converted to ammonium nitrate.

A calcium nitrate solution is also obtained when tail gases from nitric acid plants are absorbed in milk of lime. The initial nitrate – nitrite solution is converted to pure calcium nitrate solution by a reaction analogous to reaction (1.7).

3.3.1. *Calcium Nitrate from Limestoneand Nitric Acid*

In this process, limestone is mixed with 50 –60 % nitric acid (Fig. 12). Calcium nitrate is formed by the reaction

Figure 12. Production of calcium nitrate from limestone

$$CaCO_3 + 2\,HNO_3 \rightleftharpoons Ca(NO_3)_2 + H_2O + CO_2 \tag{3.2}$$

Water vapor and carbon dioxide are withdrawn from the process. Any remaining free nitric acid is then neutralized with ammonia to give ammonium nitrate; further ammonium nitrate can be added to adjust the content of this compound and to improve the storage qualities of the product. The calcium nitrate solution is then evaporated. Solid calcium nitrate can be subjected to any of the usual fertilizer processes (e.g., granulation, flocculation, or prilling).

The end product contains ca. 15.5 wt % nitrogen (0.9 % ammonium N, 14.6 % nitrate N). The main constituent (63 %) is the easily crystallized phase $NH_4NO_3 \cdot 5Ca(NO_3)_2 \cdot 10H_2O$; also present are 12 % $Ca(NO_3)_2 \cdot 2H_2O$ and 25 % calcium nitrate.

3.3.2. *Calcium Nitrate as a Byproduct of the Odda Process*

The Odda process is based on the digestion of rock phosphate with nitric acid to give phosphoric acid and calcium nitrate (Fig. 13) [61], [62]:

Figure 13. The Odda process

$$Ca_3(PO_4)_2 + 6\,HNO_3 \rightarrow 2\,H_3PO_4 + 3\,Ca(NO_3)_2 \tag{3.3}$$

The Ca^{2+} in the digester liquor is treated as a ballast. The CaO : P_2O_5 ratio serves as a measure of the ballast content and is decreased from 1.5 to 0.3 by removing the sand, with subsequent crystallization and removal of calcium nitrate. The remaining liquor (nitrophosphoric acid) is neutralized with ammonia, evaporated, granulated, classified, and conditioned (coated).

Digestion of Rock Phosphate. The digestion of rock phosphate with nitric acid is an exothermic reaction and proceeds as follows at ca. 70 °C:

$$Ca_5[(PO_4)_3F] + 10\,HNO_3 \rightarrow 5\,Ca(NO_3)_2 + HF + 3\,H_3PO_4 \tag{3.4}$$

Usually 50 – 60 % nitric acid is employed in an excess up to 20 % over the stoichiometric amount, depending on the rock phosphate grade and process.

The digestion reaction is governed by three interrelated factors: digestion temperature, particle size, and residence time in the reactor. If the temperature is too high, nitric acid may decompose to form nitrogen oxides. If the temperature is too low and the particles are too large, a longer residence time is necessary.

Crystallization of Calcium Nitrate. The CaO : P_2O_5 ratio of the digester liquor is lowered by crystallizing and removing calcium nitrate tetrahydrate $Ca(NO_3)_2 \cdot 4H_2O$ to enhance the water solubility of phosphorus pentoxide in the fertilizer. The quantity of calcium nitrate tetrahydrate obtained depends on the crystallization temperature, which is usually below 0 °C. The tetrahydrate crystals are washed with cold nitric acid and calcium nitrate – ammonium nitrate solution to recover as much of the phosphorus pentoxide content as possible. The crystals should contain less than 0.3 wt % residual phosphorus pentoxide. Experiments have shown that ca. 60 wt % nitric acid is suitable for washing. The acid is precooled to < 10 °C, sometimes as low as –5 °C, to minimize the risk of redissolving the crystals.

Any acid remaining in the crystal filter cake would interfere with the subsequent conversion of calcium nitrate tetrahydrate. It

is therefore eliminated by treatment with a solution of calcium nitrate and ammonium nitrate.

The tetrahydrate crystals are redissolved in ammonium nitrate solution. The cooling effect produced in this endothermic process and that resulting from the evaporation of ammonia are used to cool the crystallization liquor.

Either the calcium nitrate – ammonium nitrate solution is processed directly to fertilizers (see Section Calcium Nitrate from Limestoneand Nitric Acid), or the calcium nitrate is treated with ammonium carbonate to yield ammonium nitrate.

Conversion of Calcium Nitrate. Figure 14 gives the flow sheet for calcium nitrate conversion. Ammonium carbonate is obtained by reacting ammonia and carbon dioxide in a 65 % ammonium nitrate solution in an absorption tower:

Figure 14. Calcium nitrate conversion

$$2\,NH_3 + CO_2 + H_2O \rightarrow (NH_4)_2CO_3 \qquad (3.5)$$

The reaction occurs in the liquid phase and the product contains < 38 wt % ammonium carbonate.

Calcium nitrate and ammonium carbonate are then reacted at ca. 50 °C in the conversion reactor:

$$(NH_4)_2CO_3 + Ca(NO_3)_2 \rightarrow CaCO_3 + 2\,NH_4NO_3 \qquad (3.6)$$

The reactor operates with a small excess of ammonium carbonate. If the excess is too great, the precipitated lime becomes too fine and is difficult to process. With an excess of calcium nitrate, the precipitate becomes slimy and cannot be filtered. Another reason for avoiding an excess of calcium nitrate is to keep the calcium ammonium nitrate obtained by reacting lime with ammonium nitrate from becoming hygroscopic. Calcium ammonium nitrate, with lime as a filler, contains ca. 26 wt % nitrogen.

3.4. Product Forms, Storage, and Transportation

Calcium nitrate for fertilizer use is marketed as a noncaking grade that is usually treated with aryl alkyl sulfonates. Airtight bins are required for the storage of hygroscopic calcium nitrate. Coated or plastic bags are suitable for transportation. Like other nitrates, calcium nitrate must be kept away from oxidizable substances.

3.5. Uses

Calcium nitrate is employed as a nitrogen fertilizer either directly (see Section Calcium Nitrate from Limestoneand Nitric Acid) or indirectly as calcium ammonium nitrate (see Section Calcium Nitrate as a Byproduct of the Odda Process).

The combined use of calcium nitrate and urea in fertilizers has also been proposed [63], [64]. Other nitrates are obtained by reacting calcium nitrate with salts of other cations, preferably sulfates (see also Section Potassium Nitrate from Calcium Nitrate).

Calcium nitrate is employed as a granulation aid for ground basic slag, ammonium and potassium sulfates, ammonium nitrate, and other fertilizer salts. Because of its high solubility, it is used as an oxidizing additive in water-containing explosives (along with ammonium nitrate).

Addition of calcium nitrate has been suggested as a way of improving the combustion qualities of heating oil and tobacco. It is also used in the preparation of cooling brines and in wastewater treatment (see Chap. Environmental Aspects). Because of its highly endothermic heat of solution, the tetrahydrate $Ca(NO_3)_2 \cdot 4H_2O$ can be used for cooling, for example in medical applications.

3.6. Economic Aspects

The use of calcium nitrate as a fertilizer is declining worldwide. In 1978, only 170 000 t of nitrogen was consumed in this form, most of it in Scandinavia (where the important producers are located), followed by Egypt. No statistics are available on the use of calcium nitrate in the industrial sector.

[Top of Page]

4. Sodium Nitrite

Sodium nitrite is the most industrially important salt of nitrous acid.

4.1. Properties [65]

Sodium nitrite [7632-00-0], $NaNO_2$, M_r 69.00, has an enthalpy of formation of ΔH_{298} = – 358 ± 2 kJ/mol. The β allotrope is stable at 25 °C and in the pure state forms colorless rhombic crystals of space group C_{2v}^{20}; ϱ_{298} = 2.168 g/cm^3 [3]; C_p

, 298 = 63.64 J mol^{-1} K^{-1}; refractive index at 589 nm n_α = 1.35, n_β = 1.46, n_γ = 1.65. At 163 °C, this modification adapts a rhombic form of type $D_2^{25}{}_h$ (enthalpy of crystallization +1.2 kJ/mol) [66], *m p* 271 °C.

Sodium nitrite is hygroscopic (Fig. 15) [65]. The anhydrous salt has an enthalpy of solution of ΔH_{298} = +13.9 kJ/mol at infinite dilution [3]. The hydrate $NaNO_2 \cdot 0.5H_2O$ exists below –5 °C. Sodium nitrite is soluble in liquid ammonia; $2NaNO_2 \cdot NH_3$ forms below –64 °C. The solubility of sodium nitrite in 95 % ethanol at 25 °C is ca. 1.4 %.

Figure 15. Properties of a saturated solution of sodium nitrite in water

a) Density; b) Content of sodium nitrite; c) Vapor pressure

b p = boiling point of saturated solution containing 68.7 wt % sodium nitrite at 101.3 kPa and 128 °C; A = transition point: –5.1 °C, 41.6 % sodium nitrite; E = cryohydric point: –19.0 °C, 28.6 % sodium nitrite.

Sodium nitrite oxidizes slowly in air. Above 330 °C it decomposes:

$$2\,NaNO_2 \rightarrow Na_2O + NO + NO_2 \tag{4.1}$$

If the resulting nitrogen oxides are not removed, they react further with sodium nitrite:

$$NaNO_2 + NO_2 \rightleftharpoons NaNO_3 + NO \tag{4.2}$$

$$2\,NaNO_2 + 2\,NO \rightarrow 2\,NaNO_3 + N_2 \tag{4.3}$$

so that the end products of decomposition between 330 and 400 °C are sodium nitrate, sodium oxide, and nitrogen. Above 600 °C, the sodium nitrate product decomposes to oxygen and sodium nitrite (reaction 1.1), so that the end products at this temperature are sodium oxide, nitrogen, and oxygen [6].

Aqueous solutions of alkali nitrites reduce strong oxidizing agents (e.g., potassium permanganate solution), but in acidic solution they oxidize potassium iodide to iodine and Fe^{2+} to Fe^{3+}. They oxidize ammonium salts in weakly acidic solution to nitrogen above 50 °C. Urea and amidosulfonic acid are likewise oxidized to nitrogen:

$$CO(NH_2)_2 + 2\,NaNO_2 + 2\,HCl \rightarrow CO_2 + 2\,N_2 + 3\,H_2O + 2\,NaCl \tag{4.4}$$

$$SO_3H - NH_2 + NaNO_2 + HCl \rightarrow N_2 + H_2O + H_2SO_4 + NaCl \tag{4.5}$$

In anhydrous melts at 210 – 220 °C, excess sodium nitrite oxidizes urea in an exothermic reaction that yields sodium carbonate and nitrogen:

$$CO(NH_2)_2 + 2\,NaNO_2 \rightarrow Na_2CO_3 + 2\,N_2 + 2\,H_2O \tag{4.6}$$

Equimolar quantities under the same conditions form sodium cyanate:

$$CO(NH_2)_2 + NaNO_2 \rightarrow NaCNO + N_2 + 2\,H_2O \tag{4.7}$$

The $NaNO_2$ – $NaNO_3$ system forms a eutectic at 37.5 mol % sodium nitrate, *m p* 227 °C. Mixed crystals precipitate from the melt at all concentrations [67].

Nitrites do not occur in mineral form. Nitrite is formed as a metabolic product by microorganisms that oxidize organic nitrogen-containing substances; small amounts of nitrite are thus found in soil and groundwater.

4.2. Production

Until the beginning of the 20th century, sodium nitrite was produced by the reduction of sodium nitrate with lead, iron, zinc, manganese dioxide [which is oxidized to $BaMnO_4$ in the presence of Ba $(OH)_2$], coke, sulfur dioxide, and calcium carbide. Of these processes, the only one of industrial significance was the reduction of molten sodium nitrate with lead at ca. 400 °C. Other earlier processes are described in [14], [68].

Large-scale production of sodium nitrite is now based on the reaction of nitrogen oxides with sodium carbonate or sodium hydroxide solution. The molar ratio of nitrogen oxides is called the “oxidation degree” (OD):

$$\frac{[NO_2]}{[NO] + [NO_2]} \cdot 100 = OD$$

At OD < 50 %, the reaction is described by

$$2\,NaOH + NO_2 + NO \rightarrow 2\,NaNO_2 + H_2O \tag{4.8}$$

Excess nitrogen monoxide does not react but is oxidized to nitrogen dioxide by ambient oxygen. At OD > 50 % and a high partial pressure of oxygen, the following (slower) reactions also take place:

$$2\,NaOH + 2\,NO_2 \rightarrow NaNO_3 + NaNO_2 + H_2O \tag{4.9}$$

$$2\,NaOH + 3\,NO_2 \rightarrow 2\,NaNO_3 + NO + H_2O \quad (4.10)$$

The reaction with sodium carbonate proceeds analogously. In practice, nitrate formation according to reactions (4.9) and (4.10) cannot be completely prevented even at OD < 50 %.

To obtain nitrite solutions with a minimum nitrate content, the OD must be kept below 50 % [69] and the pH above 8. In an acidic environment, nitrous acid is formed and decomposes to form nitric acid:

$$3\,HNO_2 \rightarrow HNO_3 + 2\,NO + H_2O \quad (4.11)$$

If a pure nitrite solution is desired, the gas leaving the absorption columns of the nitric acid plant must first be freed of entrained nitric acid. Because nitrogen dioxide is more thoroughly and rapidly absorbed in the columns than nitrogen monoxide, the gas mixture subjected to alkaline absorption has OD < 50 % and contains 3 – 4 vol % oxygen. Alkaline absorption is described in Section Synthetic Sodium Nitrate [70].

Nitrogen oxides produced by catalytic combustion of ammonia can also be used directly for the production of sodium nitrite. If the oxygen excess is kept small and an intermediate “acid washing” step is used, the OD can be kept lower than 50 %.

4.3. Product Forms, Storage, and Transportation

Sodium nitrite is sold as the salt and in solution. The finely crystalline, slightly yellowish salt is marketed in untreated form and also after treatment with aryl alkyl sulfonates [18]. The salt contains ca. 99.0 % sodium nitrite, 0.6 % sodium nitrate, < 0.1 % sodium chloride and sodium sulfate, and < 0.1 % water.

Because of its hygroscopic nature and toxicity, sodium nitrite can be transported only in packaged form (plastic bags and metal tanks). It must be stored and shipped separately from oxidizable substances, ammonium salts, urea, food, and animal feeds. Sodium nitrite solution is marketed at a density of about 1.3 kg/L; it contains ca. 500 g/L sodium nitrite, 10 – 25 g/L sodium nitrate, and 5 g/L sodium hydrogen carbonate and has a pH of ca. 8. The solution can be stored in iron tanks.

4.4. Uses

Large amounts of sodium nitrite are consumed in the chemical and pharmaceutical industries for the production of nitroso and isonitroso compounds, diazotization reactions (especially for dyes), and the synthesis of pharmaceuticals (e.g., caffeine) and agricultural pesticides (e.g., pyramin).

Other applications of sodium nitrite are in metallurgy and corrosion prevention. It is used as an accelerator in phosphating, added to alkaline pickling solutions for aluminum, applied to steel as a descaling agent, added to drilling oils and abrasives, used for passivating metal surfaces and for creating protective coatings [e.g., of the type $Fe(NH_3)_x(NH_2)_3 \cdot yH_2O$] on carbon steels [71], and added as a corrosion inhibitor to lubricating oils and greases as well as to cooling water loops. Sodium nitrite serves as an oxidizing agent in the alkaline detinning of tinplate scrap [72] and a corrosion inhibitor in heat-transfer baths (see Section Uses).

Sodium nitrite is used in lubricants for glass-forming equipment [73]. Like sodium nitrate and potassium nitrate, it is used as a heat-transfer medium.

Sodium nitrite is recommended as an additive in concrete and gypsum to improve strength and combat the corrosion of iron reinforcement.

In curing salts used in the food industry, sodium nitrite is still the most reliable agent for protecting against botulism, a dangerous bacterial contaminant of meats. High nitrite concentrations can, however, lead to the formation of carcinogenic nitrosamines; legislative restrictions have, therefore, been imposed on the use of nitrite. Methods have been developed for achieving a satisfactory effect with minimal quantities [74]. The simultaneous addition of other substances (e.g., ascorbic acid) is reported to prevent the formation of nitrosamines [75], [76].

4.5. Economic Aspects

Sodium nitrite is produced as an important intermediate by the chemical industry in many countries, usually in conjunction with nitric acid production. Production statistics are not available.

[Top of Page]

5. Potassium Nitrite

5.1. Properties [77]

Potassium nitrite [7758-09-0], KNO_2, M_r 85.10, has an enthalpy of formation of ΔH_{298} = –375 ± 5 kJ/mol. The anhydrous product forms colorless monoclinic crystals of space group C^3_s, which are stable at 25 °C, ϱ_{298} = 1.915 g/cm^3 [3], *mp* 440 °C [3] (decomposition begins below the melting point).

Potassium nitrite is highly hygroscopic (Fig. 16) [78]; the enthalpy of solution of the anhydrous salt is ΔH_{298} = +13.4 kJ/mol at infinite dilution [2]. The hydrate $KNO_2 \cdot 0.5H_2O$ exists below –8.9 °C.

Figure 16. Properties of a saturated solution of potassium nitrite in water

a) Density; b) Content of potassium nitrite

bp = boiling point of saturated solution containing 82.0 wt % potassium nitrite at 100.9 kPa and 132 °C; A = transition point: –8.9 °C, 71.9 % potassium nitrite; E = cryohydric point: –40.2 °C, 64.9 % potassium nitrite.

Thermal decomposition of potassium nitrite yields nitrogen oxides and is analogous to that of sodium nitrite but begins at ca. 410 °C [6].

The system KNO_2 – KNO_3 has a eutectic point at 316 °C and 22.5 mol % potassium nitrite [79]. In the quaternary system KNO_2 – KNO_3 – $NaNO_3$ – $NaNO_2$, the composition with the lowest freezing point (142 °C) is 37.5 mol % potassium nitrite, 37.5 mol % sodium nitrate, and 25 mol % sodium nitrite [80], [23].

5.2. Production

Potassium nitrite can be obtained by reduction of potassium nitrate (similarly to sodium nitrite). A variety of other reactions between sodium nitrate and potassium salts have also been described [77]. Production of potassium nitrite by absorption of nitrogen oxides in potassium hydroxide or potassium carbonate solution is not employed on a large scale because of the high price of these alkalies. Furthermore, the fact that potassium nitrite is highly soluble in water makes the solid salt difficult to recover. The solubility relationships in the system KNO_2 – KNO_3 – H_2O are described in [81].

5.3. Uses

Potassium nitrite is used only in very small quantities, for example, as an oxidizing agent and as a corrosion inhibitor in washing with hot potash for removal of carbon dioxide from gas streams (e.g., synthesis gas). Potassium nitrite is more soluble than sodium nitrite and does not form sparingly soluble bicarbonate in carbon-dioxide-rich solutions.

[Top of Page]

6. Ammonium Nitrite

Ammonium nitrite is a very unstable compound that is virtually always handled in aqueous solution.

6.1. Properties

Ammonium nitrite [13446-48-5], NH_4NO_2, M_r 64.04 [3], has an enthalpy of formation of ΔH_{298} = –260 ± 5 kJ/mol and forms cubic crystals, ϱ_{298} = 1.69 g/cm^3 [3]. The melting point is not well defined because of decomposition.

Ammonium nitrite is highly hygroscopic and readily soluble in water [78] (enthalpy of solution ΔH_{285} = +19.3 kJ/mol at infinite dilution [3]). The saturated solution contains 42.5 wt % ammonium nitrite at the cryohydric point (–27.9 °C), 55.4 % at 0 °C, and 65.0 % at 20 °C. Hydrated solid phases are not known.

Solid ammonium nitrite is stable only in the pure, dry state. Exothermic decomposition begins at 60 °C and may occur explosively:

$$NH_4NO_2 \rightarrow N_2 + 2\,H_2O\ \Delta H = -300\,\mathrm{kJ/mol} \tag{6.1}$$

The saturated solution is stable only up to 30 °C; dilute solutions release nitrogen according to reaction (6.1) above 60 °C. Decomposition involves nitrous acid as an intermediate [82]; the stability of the aqueous solution is enhanced by the addition of ammonia, calcium hydroxide, or potassium iron(II) cyanide.

Dilute ammonium nitrite solutions can be inverted with nitric acid below 30 °C [83]:

$$3\,NH_4NO_2 + 2\,HNO_3 \rightarrow 3\,NH_4NO_3 + 2\,NO + H_2O \tag{6.2}$$

Mixed crystals of ammonium nitrite and ammonium nitrate precipitate from an aqueous solution of NH_4NO_2 – NH_4NO_3 containing > 47 % ammonium nitrite at 20 °C [84]. The most highly concentrated solution in this system at 20 °C contains only 6 % water, 48 % ammonium nitrite, and 46 % ammonium nitrate.

6.2. Production

Ammonium nitrite is produced and utilized industrially solely in the form of a weakly ammoniacal solution with pH > 7.5. When ammonium nitrite solution is prepared, the simultaneous formation of ammonium nitrate must be avoided because the two compounds cannot be separated from one another.

Ammonium nitrite is produced on an industrial scale from nitrogen oxides and ammonia or ammonium carbonate. The reaction is similar to that used for the formation of sodium nitrite. Because of the instability of ammonium nitrite (reaction 6.1), however, care must be taken to keep the pH between 8 and 9 and the temperature between 0 and + 5 °C.

The heat balance of ammonium nitrite formation depends strongly on the feed ammonium compound:

$$2\,NH_3 + NO_2 + NO + H_2O \rightarrow 2\,NH_4NO_2\ \Delta H_{298} = -77.5\,\mathrm{kJ} \tag{6.3}$$

$$(NH_4)_2CO_3 + NO_2 + NO \rightarrow 2\,NH_4NO_2 + CO_2\ \Delta H_{298} = -47\,kJ \quad (6.4)$$

$$2\,NH_4HCO_3 + NO_2 + NO \rightarrow 2\,NH_4NO_2 + CO_2 + H_2O\ \Delta H_{298} = -13.5\,kJ \quad (6.5)$$

Use of ammonium bicarbonate appears advantageous because no water is formed in the reaction to dilute the solution. However, since it has a low solubility the use of ammonium carbonate is generally preferred.

The process is usually carried out under an overpressure of 0.1 – 0.6 kPa [85]. The NO_2 – NO gas mixture is first cooled to 0 °C to decrease the degree of oxidation (see Section Production) to 35 – 40 % by condensation of dilute nitric acid, and then fed into absorption columns connected in series and packed with ceramic Raschig rings or fitted with sieve trays. The circulating solution is held at ca. 0 °C by coolers located at the bottoms of the columns and outside them. To prevent crystallization of ammonium bicarbonate, a metered amount of aqueous ammonia solution is added along with the ammonium carbonate. The final product solution has a pH of 8 and contains ca. 150 – 200 g/L ammonium nitrite, 20 g/L ammonium nitrate, 20 g/L ammonium carbonate, and 2 – 5 g/L ammonia. Ammonium nitrite mist is formed in the absorption step, a final gas scrub is therefore used to recover ammonium carbonate solution for reuse [86].

The ammonium nitrite yield relative to the nitrogen oxides inlet to ammoniacal absorption is less than 90 %. Losses include nitrate formation, nitrite decomposition (reaction 6.1), and tail-gas and mist losses.

6.3. Uses

Ammonium nitrite can be used to passivate steam boiler equipment and chemical plants because it does not leave any nonvolatile residues behind. It is also used as a blowing agent in the manufacture of hollow rubber articles. In the laboratory, very pure nitrites can be prepared from pure ammonium nitrite and the hydroxides of other cations.

7. Calcium Nitrite

7.1. Properties [87]

Calcium nitrite, [13780-06-8], $Ca(NO_2)_2$, M_r 132.09, has an enthalpy of formation of ΔH_{298} = –750 ± 10 kJ/mol, ϱ_{273} = 2.26 g/cm^3 [78], *mp* 398 °C (decomposition begins below melting point).

Anhydrous calcium nitrite is hygroscopic and dissolves readily in water (Fig. 17) [78]; the enthalpy of solution for 1 mol in 800 mol of water is ΔH_{293} = –8.5 kJ/mol. The monohydrate crystallizes from solution below 129 °C to form silky hexagonal needles (ϱ_{293} = 2.23 g/cm^3).

Figure 17. Properties of a saturated solution of calcium nitrite in water

a) Density; b) Content of calcium nitrite

bp = boiling point of saturated solution at 101.3 kPa and 133 °C with decomposition; A = first transition point: $Ca(NO_2)_2 \cdot 4H_2O + Ca(NO_2)_2 \cdot H_2O$ at + 34.6 °C and 55.1 % $Ca(NO_2)_2$; B = second transition point: $Ca(NO_2)_2 \cdot H_2O + Ca(NO_2)_2$ at + 129 °C and 71 % $Ca(NO_2)_2$; E = cryohydric point: ice + $Ca(NO_2)_2 \cdot 4H_2O$ at –20.0 °C and 34.2 % $Ca(NO_2)_2$.

Below 34.6 °C, the tetrahydrate $Ca(NO_2)_2 \cdot 4H_2O$ crystallizes in tetragonal form: ϱ_{293} = 1.72 g/cm^3, enthalpy of solution for 1 mol in 800 mol of water ΔH_{293} = + 33.5 kJ/mol.

Calcium nitrite decomposes to calcium oxide and a mixture of nitrogen monoxide and nitrogen dioxide at temperatures as low as 250 °C [6]. The hydrates are decomposed by atmospheric carbon dioxide, with the formation of nitrogen oxides. A saturated solution of calcium nitrite boils at 133 °C (101.3 kPa) with decomposition.

7.2. Production

Calcium nitrite is formed when a mixture of gaseous nitrogen dioxide and nitrogen monoxide (OD < 50 %) is absorbed in a suspension of calcium hydroxide. This process is used to clean up the final tail gases from low-pressure nitric acid plants when no demand exists for sodium nitrate or sodium nitrite. The spent absorption liquor contains calcium nitrite and generally some calcium nitrate. The nitrite can be recovered as the tetrahydrate $Ca(NO_2)_2 \cdot 4H_2O$ by concentration and cooling. This product has a lower solubility than calcium nitrate tetrahydrate $Ca(NO_3)_2 \cdot 4H_2O$. The nitrite is not, however, recovered on a large scale; the calcium nitrite solution is usually inverted with nitric acid to obtain calcium nitrate.

7.3. Uses

No large-scale application exists for calcium nitrite. Calcium nitrite is reacted with the sulfates of other cations. The corresponding nitrite solutions are obtained after removal of the precipitated gypsum by filtration. Calcium nitrite mixed with calcium nitrate and calcium chloride is recommended as a noncorrosive salt for thawing ice on roads (along with $NaNO_2$). Calcium nitrite is proposed as a corrosion-inhibiting additive in concrete that also improves workability at low temperature.

[Top of Page]

8. Analysis of Nitrates and Nitrites

Nitrate Determination [88], [89]. For *volumetric determination*, nitrate is reacted in strongly alkaline solution with Devarda's alloy (50 % Cu + 45 % Al + 5 % Zn) or in neutral solution with Arnd's alloy (65 % Cu + 35 % Mg) and thus converted to ammonia. The ammonia is distilled into a receiver containing sulfuric acid and determined by acidimetric methods. Ammonium and nitrite are also detected and must, therefore, be determined separately. The method is not applicable in the presence of urea, urea – aldehyde condensates, cyanamide, or protein.

Gravimetrically, nitrate is determined as nitron nitrate after precipitation with nitron in acetic acid solution. Perchlorate, chlorate, nitrite, and other anions precipitate along with nitrate. The method cannot be used in the presence of urea – aldehyde condensates and protein.

At low concentrations (ppm range), nitrate is determined *photometrically* with 2,4-dimethylphenol, brucin, or sodium salicylate. Nitrite interferes and must be removed.

The *potentiometric method* with a nitrate ion-sensitive electrode is suitable for the determination of nitrate in single samples and for automated continuous monitoring (e.g., of wastewater) [90]. Perchlorate, iodide, chlorate, and bromide ions as well as high nitrite concentrations interfere with the method.

Nitrate can be determined in the presence of nitrite by *titrimetry* after reduction with iron(II) sulfate; the end point is indicated potentiometrically [91].

Prior to nitrate determination, nitrite can be destroyed in a weakly acidic medium with ammonium salts, urea, sodium azide, amidosulfonic acid, or hydroxylamine (cf. reactions 4.4 and 4.5).

Ion chromatography is an effective method for determining and separating nitrate [92]. The nitrate ion is detected either with a conductivity detector or a UV detector (excitation wavelength 254 nm). This technique has the advantages of high precision, rapidity, and independence of flow rate [93].

Nitrite Determination. High nitrite concentrations are determined by titration at ca. 35 °C with potassium permanganate in sulfuric acid solution. To avoid loss of nitrite, the solution is allowed to flow with stirring into acidified potassium permanganate solution until it becomes colorless [88]. Other ions that can be oxidized by potassium permanganate in sulfuric acid solution must be considered in evaluating the results.

Low contents of nitrite are determined photometrically with sulfanilamide and *N*-(1-naphthyl)ethylenediammonium dichloride as a red azo dye [94]. The reaction is specific for nitrite and can be automated [95]. This method is recommended for series analyses (e.g., of water samples).

Determination of Cations.
Sodium as the primary constituent can be determined gravimetrically by precipitation with uranyl magnesium acetate. This method can be employed even with a large excess of potassium [89]. Flame photometry and atomic absorption spectroscopy can be used for lower concentrations and in the trace range.

Potassium is precipitated as sparingly soluble potassium tetraphenyl borate and determined as such by weighing after treatment with sodium tetraphenyl borate in weakly alkaline or acidic solution [96-98]. Volumetric determination of potassium with sodium tetraphenyl borate and an electrometric end point indication is also important [98-100]. The chloroplatinate method is employed in the United States [89], [100].

Thermometry measures the heat (ca. –50 kJ/mol) released when potassium is precipitated as the perchlorate [101]. Potassium is also determined by conductometric titration with sodium tetraphenyl borate [98].

The potassium content can be determined quickly in process analysis by flame photometry [89] and atomic absorption spectroscopy. In the plant, β or γ radiation of ^{40}K solid salts or a solution can be utilized for analysis, product inspection, and process control [102].

Ammonium is determined acidimetrically by distillation of ammonia from alkaline solution. Trace amounts can be determined by photometry after formation of indophenol or reaction with Nessler's reagent [94]. Potentiometric determination with an ammonia electrode is suitable for all concentration ranges [90].

Calcium and magnesium in nitrates and nitrites are determined volumetrically by titration with the demineralized disodium salt of ethylenediaminetetraacetic acid. Other divalent cations must first be masked or precipitated [103].

Determination of Impurities. *Water content* can be measured either by the Karl Fischer method or by determination of the weight loss at 105 °C [89].

High concentrations of *chloride* are determined volumetrically by titration with silver nitrate [89]; trace amounts are measured by titration with mercury(II) nitrate and diphenylcarbazone as indicator [100]. A photometric technique is based on the determination of iron(III) rhodanide formed after liberation of rhodanide ion from mercury(II) rhodanide by chloride ion [95]. Very low concentrations can be determined turbidimetrically as silver chloride at 420 nm. This has the advantage that toxic mercury is not involved in the analysis.

Chlorate can be determined iodometrically in strong hydrochloric acid solution. *Perchlorate* is determined gravimetrically as potassium perchlorate [89]. *Iodate* can be determined iodometrically in weakly acidic solution. (Nitrite ion must be destroyed before iodometric analyses are performed.)

Boric acid can be determined by acidimetric titration, either directly or after isolation as methyl borate in the presence of mannitol or glycerol [89].

[Top of Page]

9. Environmental Aspects

Nitrate Removal. Nitrates are undesirable in wastewater for two reasons: uncontrolled denitrification can interfere with the final clarification step in biological wastewater treatment plants, and high nitrate concentrations can cause contamination of drinking water.

In 1970 the World Health Organization (WHO) issued guidelines recommending that the maximum limit for nitrate concentrations should be 50 mg/mL, this was later reduced to 45 mg/mL. The WHO also recommended a maximum acceptable concentration of 100 mg/L [105]. In the United States the EPA proposed regulations for drinking water on May 22, 1989 [106]. Public comment closed August 21, 1989, and the final rule was scheduled for December 1990. A maximum containment level for total nitrate and nitrite of 10 mg/L (as nitrogen) is proposed. As early as July 1980, the Council of the European Community issued a directive concerning the quality of water for human consumption [107]. The maximum permissible nitrate concentration was set at 50 mg/L, with a guide level of only 25 mg/L. Member countries agreed that drinking-water quality would meet this standard within five years (for the members Portugal, Spain, and Greece, who joined the EC later, the appointed five-year period started in 1988). To achieve this, some waterworks dilute their water with low-nitrate water; the trend to equip waterworks with nitrate removal facilities is also increasing. Because this equipment is very expensive, nitrate removal from wastewater before it reaches the treatment plant and reduction in nitrate loading of surface waters (agricultural) are desirable goals; see also ⟶ Fertilizers – Nitrogen. Three methods have been described for the removal of nitrates from wastewater: reverse osmosis, anion exchange, and denitrification.

Reverse Osmosis. The principles of reverse osmosis are described elsewhere (⟶ Membranes and Membrane Separation Processes – Principle of Reverse Osmosis). Pressure is used to force water through a membrane that is impermeable to any dissolved solutes or suspended solids. Despite its high cost, reverse osmosis is becoming more and more important in wastewater treatment; the cost depends on the nature of the inlet wastewater stream (pretreatment). If the wastewater has a high suspended solid content or the dissolved salts might crystallize, reverse osmosis can only be used to a limited extent because the membranes may become plugged. This technique results in the production of a concentrated nitrate solution, which is then dealt with by other methods.

Anion Exchange. Units based on anion-exchange resins [108] can only be used in special cases, because of their inadequate selectivity for nitrate versus chloride ions. The same is true for a process developed especially for the removal of nitrate from wastewater in cellulose nitrate production, which utilizes water-insoluble secondary amines in the chloride form as liquid ion exchangers [109]. In contact with wastewater, these substances exchange chloride for nitrate. In the next step, the amines exchange their nitrate ions for chloride ions from a potassium chloride solution to yield pure potassium nitrate as a byproduct. This technique, however, requires virtually chloride-free wastewater. A similar procedure has been described in which the amine is used in the sulfate form and ammonium nitrate is obtained as byproduct after stripping with ammonia gas [110].

Denitrification. Denitrification is currently the most important process for nitrate removal [111-114]. Nitrate is reduced to nitrogen by facultatively anaerobic bacteria (e.g., *Achromobacter*, *Denitrobacillus, Nitrococcus, or Spirillum*) under anaerobic conditions. These bacteria can use nitrate and nitrite as a source of oxygen.

$$2\,NO_3^- + 10\,H^+ + 10\,e^- \rightarrow 2\,OH^- + 4\,H_2O + N_2 \qquad (9.1)$$

$$2\,NO_2^- + 6\,H^+ + 6\,e^- \rightarrow 2\,OH^- + 2\,H_2O + N_2$$

To maintain metabolism, an adequate supply of carbohydrates must be present or added. The carbohydrates are oxidized to carbon dioxide and water.

Denitrification is the sole metabolic route for converting fixed nitrogen to the molecular form. The required anaerobic conditions are considered satisfied if the BOD_5 value (five-day biological oxygen demand) is more than 1.5 times the oxygen fixed in the nitrate.

Nitrite Removal. Nitrites must be removed from wastewater because they are toxic (see Chap. Toxicology and Occupational Health) and also because they interfere with the oxygen economy of natural waters and water treatment plants. Nitrite ions can be eliminated by oxidation to nitrate, by reduction to elemental nitrogen, or by denitrification (see Nitrate Removal).

Oxidation to Nitrate. Nitrite is reacted with, for example, sodium hypochlorite in a weakly acidic medium (pH 3 – 4):

$$NaNO_2 + NaOCl \rightarrow NaNO_3 + NaCl \qquad (9.2)$$

This process has the advantage of a high reaction rate with virtually 100 % conversion. It can be used as a continuous method through relatively simple redox potential measurements and automation. It has the drawback, however, of increasing the sodium chloride content of water [115].

Another option is oxidation with hydrogen peroxide:

$$NaNO_2 + H_2O_2 \rightarrow NaNO_3 + H_2O \qquad (9.3)$$

This reaction occurs at pH 3 – 3.5 and can be effected only in batch operation because a stepwise measurement and hydrogen peroxide metering cycle must be used. The process has the advantages of low cost and no salting (Table 7) [115].

Table 7. Comparison of nitrite removal processes using hydrogen peroxide and sodium hypochlorite [110]

	Hydrogen peroxide	Sodium hypochlorite
Batch operation	yes	yes
Continuous operation	no	yes
pH	2.0 – 4.0	3.0 – 3.5
Concentration of oxidizing agent, wt %	35	12.5
Oxidizing agent required, kg/kg nitrite	2.25	13.5
Cost of oxidizing agent, DM/kg nitrite	3.85	6.48
Salt produced, kg/kg nitrite	0	2.5 NaCl
Loss of active agent on storage	no	yes

Nitrite is also oxidized to nitrate by *Nitrobacter* species under aerobic conditions:

$$NO_2^- + 1/2\,O_2 \rightarrow NO_3^-$$

Reduction to Nitrogen. Nitrites can be reduced to nitrogen with amidosulfuric acid:

$$NaNO_2 + NH_2SO_2OH \rightarrow N_2 + NaHSO_4 + H_2O \qquad (9.4)$$

This reaction is of value for high nitrite levels and is carried out at ca. pH 4. Urea is also employed as reducing agent (reactions 4.4. and 4.5).

[Top of Page]

10. Toxicology and Occupational Health [116]

Nitrates and nitrites cause relaxation of smooth muscle cells [117, pp. 224 – 244], which can be so drastic that the contractile system is totally inhibited (protein phosphorylation). These compounds have a vasodilative action, allowing blood to pool in the veins so that the heart is not completely filled. The systolic blood pressure therefore drops, and the pulse rate increases. Dilation of blood vessels in the brain leads to headaches. Acute circulatory collapse and fainting are possible. Dilation of vessels in the retina leads to vision disorders.

Acute, severe poisoning is associated with a critical drop in blood pressure, vomiting, and cyanosis, and ends in death due to respiratory and circulatory failure. Methemoglobin produced by reaction of inorganic nitrite or amyl nitrite with hemoglobin is responsible for this effect. Nitrates are converted to nitrites by microbes in the intestines. Methemoglobin prevents oxygen transport because its central heme group contains a Fe^{3+} ion which is incapable of binding oxygen. Only hemoglobin (Hb) with its central Fe^{2+} ion can bind oxygen reversibly:

$$Hb \cdot Fe^{2+} \cdot O_2 \rightleftharpoons Hb \cdot Fe^{3+} \cdot OH^-$$

In the presence of nitrite, coupled oxidation occurs [117, p. 650]. Oxygen is transferred from the hemoglobin to nitrite with the formation of nitrate and methemoglobin (Fe^{3+}). In intact erythrocytes methemoglobin is reduced by enzymes (diaphorase, methemoglobin reductase).

Methemoglobin formation occurs more readily in premature and newborn babies than in adults. The intestinal flora of babies differs from that of adults and has a higher reducing capacity; nitrate is therefore more easily reduced to nitrite. In the fetus hemoglobin is more readily oxidized than in adults and the erythrocyte reductase system is not fully developed [118]. Vegetables fertilized with nitrate or tap water containing nitrate can cause methemoglobinemia in babies.

Severe intoxication is expected at an oral dosage level > 2 g. A single oral dose of 4 g of nitrite is lethal in humans [119]. In the event of poisoning, the stomach should be pumped and a physician notified [117, p. 250], [120], [121].

Nitrosamines cause tumor formation in animals that depends on dosage and route of administration. Nitrosamines are classified as risk factors for tumor formation in humans.

In the stomach secondary and tertiary amines can react with nitrite to form nitrosamines. Secondary amines are formed during cooking (roasting, frying) of proteins and alcoholic fermentation, and are constituents of flavoring substances. Low nitrosamine concentrations are found in pickled meat, alcoholic beverages, and tobacco smoke. Tetracycline contains groups that can be nitrosylated. The drug aminophenazone has been withdrawn from the market on account of its nitrosamine content (*N*-nitrodimethylamine).

1. Nitric Acid

1.1. Introduction

Nitric acid is a strong acid that occurs in nature only in the form of nitrate salts. When large-scale production of nitric acid began, sodium nitrate (soda saltpeter, Chile saltpeter) was used as the feedstock. At the beginning of the 20th century the reserves of Chile saltpeter were thought to be nearing exhaustion, so processes were developed for replacing nitrogen from natural nitrates with atmospheric nitrogen. Three techniques were used industrially:

1) Production of nitrogen monoxide by reacting atmospheric nitrogen and oxygen at > 2000 °C (direct processes)
2) Production of ammonia by hydrolysis of calcium cyanamide under pressure
3) Production of ammonia from nitrogen and hydrogen

The direct combustion of air in an electric arc, developed by Birkeland and Eyde, was abandoned because of its poor energy efficiency. Later direct processes, such as thermal nitrogen monoxide synthesis with fossil fuels or nitrogen monoxide synthesis in nuclear reactors, did not gain widespread acceptance. Ammonia production from calcium cyanamide was of only transitory value. Ammonia produced from nitrogen and hydrogen by the Haber – Bosch process (→ Ammonia) is, however, still used as feedstock for nitric acid production.

The crucial step in nitric acid production, the catalytic combustion of ammonia, was developed by Ostwald around the turn of the century. The most important design parameters for a nitric acid plant were determined first in laboratory tests and later in a pilot plant. The first production facility employing the Ostwald process came on stream in 1906 at Gerthe in Germany [1–3].

Most of the nitric acid produced is used to form inorganic fertilizers (→ Phosphate Fertilizers); it is mostly neutralized with ammonia to form ammonium nitrate (→ Ammonium Compounds, Chap. 1.2.1.).

1.2. Properties

Nitric acid was known to the ancient Egyptians because of its special ability to separate gold and silver. Many well-known alchemists in the Middle Ages experimented with the acid. In the middle of the 17th century, GLAUBER reported its preparation from saltpeter and sulfuric acid.

Physical Properties. Nitric acid [*7697-37-2*], M_r 63.013, is miscible with water in all proportions. At a concentration of 69.2 wt %, it forms a maximum-boiling azeotrope with water. The azeotropic mixture boils at 121.8 °C. Pure anhydrous nitric acid boils at 83 – 87 °C; the reason a range of boiling points are cited in the literature is that the acid decomposes on heating [4]:

$$4\,HNO_3 \longrightarrow 2\,H_2O + 4\,NO_2 + O_2$$

The nitrogen dioxide formed on decomposition colors the acid yellow or even red at higher concentrations. Because the vapors can also absorb moisture, the term "red fuming nitric acid" is used. In the pure anhydrous state, nitric acid is a colorless liquid.

The most important physical properties of pure nitric acid follow:

fp	−41.59 °C
bp	82.6 ± 0.2 °C
Density, liquid	
at 0 °C	1549.2 kg/m^3
at 20 °C	1512.8 kg/m^3
at 40 °C	1476.4 kg/m^3
Refractive index n_D^{24}	1.3970
Dynamic viscosity	
at 0 °C	1.092 mPa · s
at 25 °C	0.746 mPa · s
at 40 °C	0.617 mPa · s
Surface tension	
at 0 °C	0.04356 N/m
at 20 °C	0.04115 N/m
at 40 °C	0.03776 N/m
Thermal conductivity (20 °C)	0.343 W m^{-1} K^{-1}
Standard enthalpy of formation	
Liquid	2.7474 J/g
Gas	2.1258 J/g
Heat of vaporization (20 °C)	626.3 J/g
Specific heat	
at 0 °C	1.7601 J g^{-1} K^{-1}
at 20 °C	1.7481 J g^{-1} K^{-1}

The decomposition of nitric acid makes its physical properties difficult to determine at higher temperature. Up to ca. 50 °C, conventional methods of measurement are possible; beyond this, indirect thermodynamic calculations or special short-time measuring methods must be employed. Figure 1 illustrates the vapor pressure curve of pure nitric acid. Table 1 lists important physical properties of aqueous nitric acid. A comprehensive review of the physical and chemical properties of nitric acid is given in [6].

Figure 1. Vapor pressure curve for pure nitric acid

Chemical Properties. Concentrated nitric acid, with nitrogen in the +5 oxidation state, acts as a strong oxidizing agent. The reaction

$$NO_3^- + 4\,H^+ \rightleftharpoons NO + 2\,H_2O$$

goes to the right for all substances with oxidation potentials more negative than +0.93 V [7]. For example, copper (+0.337 V) and silver (+0.799 V) are dissolved by nitric acid, whereas gold (+1.498 V) and platinum (+1.2 V) are resistant. In practice, 50 % nitric acid (aqua fortis)

Table 1. Physical properties of aqueous nitric acid as a function of composition [5]

90	1.4826	−60	102.0	3.6	0.03
100	1.5129	−42	86.0	6.0	0

is used for separating gold from silver. Some base metals, such as aluminum and chromium, are attacked by nitric acid only at their surfaces because a thin oxide layer is formed, which protects (i.e., passivates) the core against further oxidation. As a result of this passivation, alloyed steel equipment can be used in nitric acid technology.

Highly diluted nitric acid is almost completely dissociated

$$HNO_3 + H_2O \rightleftharpoons H_3O^+ + NO_3^-$$

and does not attack copper and more noble metals. Due to its acid nature, however, it reacts with base metals, liberating hydrogen and forming nitrates.

A mixture (volume ratio 3 : 1) of concentrated nitric acid and concentrated hydrochloric acid (aqua regia) also dissolves gold.

1.3. Industrial Production

The industrial production of nitric acid by the Ostwald process is described in this section. The process involves three chemical steps (Fig. 2):

1) Catalytic oxidation of ammonia with atmospheric oxygen to yield nitrogen monoxide:

$$4\,NH_3 + 5\,O_2 \longrightarrow 4\,NO + 6\,H_2O \quad (1)$$

2) Oxidation of the nitrogen monoxide product to nitrogen dioxide or dinitrogen tetroxide:

$$2\,NO + O_2 \longrightarrow 2\,NO_2 \rightleftharpoons N_2O_4 \quad (2)$$

3) Absorption of the nitrogen oxides to yield nitric acid:

$$3\,NO_2 + H_2O \longrightarrow 2\,HNO_3 + NO \quad (3)$$

Figure 2. Ostwald process

The way in which these three steps are implemented characterizes the various nitric acid processes. In *monopressure (single-pressure) processes*, ammonia combustion and NO_x absorption take place at the same working pressure. These include medium-pressure (230 – 600 kPa) and high-pressure (700 – 1100 kPa) processes. Very few plants currently employ low pressure (100 – 220 kPa) for both combustion and absorption.

In *dual-pressure (split-pressure) processes*, the absorption pressure is higher than the combustion pressure. Modern dual-pressure plants feature combustion at 400 – 600 kPa and absorp-

tion at 900 – 1400 kPa. Some older plants still employ atmospheric combustion and medium-pressure absorption.

Intensive work on ammonia combustion as well as the oxidation and absorption of nitrogen oxides has been well documented since the early 1920s. Up to now the combustion of ammonia has been considered as a heterogeneous catalytic surface reaction with undesirable side reactions. The oxidation of nitrogen monoxide is a rare example of a homogeneous third-order gas-phase reaction. The absorption of NO_x is a heterogeneous reaction between fluid (i.e., gas and liquid) phases.

1.3.1. Oxidation of Ammonia

The oxidation of ammonia to nitrogen monoxide is described by the equation

$$4\,NH_3 + 5\,O_2 \longrightarrow 4\,NO + 6\,H_2O \quad \Delta H = -904\,\text{kJ/mol} \quad (4)$$

Over a suitable catalyst, 93 – 98 % of the feed ammonia is converted to nitrogen monoxide. The remainder participates in undesirable side reactions leading to dinitrogen monoxide (nitrous oxide, laughing gas)

$$4\,NH_3 + 4\,O_2 \longrightarrow 2\,N_2O + 6\,H_2O \quad \Delta H = -1105\,\text{kJ/mol} \quad (5)$$

and to nitrogen

$$4\,NH_3 + 3\,O_2 \longrightarrow 2\,N_2 + 6\,H_2O \quad \Delta H = -1268\,\text{kJ/mol} \quad (6)$$

Other undesirable reactions are the decomposition of the nitrogen monoxide product

$$2\,NO \longrightarrow N_2 + O_2 \quad \Delta H = -90\,\text{kJ/mol} \quad (7)$$

and its reaction with ammonia

$$4\,NH_3 + 6\,NO \longrightarrow 5\,N_2 + 6\,H_2O \quad \Delta H = -1808\,\text{kJ/mol} \quad (8)$$

Reaction Mechanism. Early theories of the mechanism for the oxidation of ammonia differed as to which intermediate product was formed. The classical theories were proposed by Andrussov (nitroxyl theory, 1926), Raschig (imide theory, 1927), and Bodenstein (hydroxylamine theory, 1935) [3]. According to the hydroxylamine theory, ammonia reacts with atomic oxygen adsorbed on the catalyst to yield hydroxylamine. This in turn reacts with molecular oxygen to form nitrous acid, which then dissociates to nitrogen monoxide and hydroxyl ions:

$$O_2 \rightleftharpoons 2\,O\ (\text{adsorb.})$$

$$O\ (\text{adsorb.}) + NH_3 \longrightarrow NH_2OH$$

$$NH_2OH + O_2 \longrightarrow HNO_2 + H_2O$$

$$HNO_2 \longrightarrow NO + OH^-$$

$$2\,OH^- \longrightarrow H_2O + O$$

In oxidation experiments under high vacuum, Bodenstein and coworkers detected both hydroxylamine and nitrous acid as intermediate products on the platinum catalyst. Later studies with a mass spectrometer showed that no such intermediate products are found above 400 °C [8]. In these tests, both molecular and atomic oxygen was found on the catalyst surface. A direct reaction between oxygen and ammonia was therefore postulated according to the following equations:

$$NH_3 + O_2 \longrightarrow NO + H_2O + H$$

$$NH_3 + O \longrightarrow NO + H_2 + H$$

In fast reactions such as the combustion of ammonia (the reaction time for Eq. 4 is ca. 10^{-11} s), however, the possible intermediates most likely cannot be detected because they are very short-lived and present in very low concentrations. Nowak [9] has compared the numerous theories of ammonia combustion. Pignet and Schmidt present a classical Langmuir – Hinshelwood treatment of the process [10]. The possibility that the combustion of ammonia may be considered as a homogeneous catalytic reaction is now being discussed.

At low temperature (200 – 400 °C), the rate of ammonia oxidation is limited by the reaction kinetics. The byproducts nitrogen, and especially dinitrogen monoxide, are formed preferentially. Between 400 and 600 °C, the reaction rate becomes limited by mass transfer, which is then dominant above 600 °C. Control by mass transfer relates to the diffusion rate of ammonia through the gas film to the catalyst surface. The product in this reaction regime is nitrogen monoxide.

The catalyst surface experiences a very low partial pressure of ammonia and a diminished partial pressure of oxygen due to mass-transfer limitations. The catalytic side reaction between ammonia and nitrogen monoxide is accelerated by an increase in the partial pressures of both species on the catalyst surface. If catalyst poisoning occurs,the number of active centers decreases and the partial pressure, particularly that of ammonia, increases at the remaining active centers. The result is increased formation of undesirable byproducts. In practice, this shift is offset by raising the temperature, i.e., the reaction is again displaced into the region limited by gas-film diffusion.

Figure 3. Photograph of platinum – rhodium gauze (Degussa, FRG) taken with a scanning electron microscope (enlargement 100 : 1)
A) Initial stage; B) Highly activated stage

Precious-metal catalysts are usually employed in the form of closely stacked, fine-mesh gauzes. At the beginning of a campaign they have a smooth surface and therefore only slightly limit mass transfer in the gas phase. This gives an initially lower yield of nitrogen monoxide. After a short time in service, however, the surface area of the catalyst increases greatly because of microstructural changes and interactions with volatilizing constituents of the catalyst (Fig. 3). Catalyst growth increases the limitation of mass transfer in the gas phase and thus the yield of nitrogen monoxide.

Reaction Engineering. From an engineering standpoint, the combustion of ammonia is one of the most efficient catalytic reactions (maximum possible conversion 98 %). According to the stoichiometry of Equation (4), the ammonia – air reaction mixture should contain 14.38 % ammonia. A lower ammonia – air ratio is, however, employed for a variety of reasons, the most important being that conversion decreases with too high a ratio; ammonia and air also form an explosive mixture. Because the mixing of ammonia and air in industrial practice is incomplete, locally higher ratios may occur. A ratio that includes a safety margin below the explosion limit is therefore necessary. The explosion limit declines with pressure so that high-pressure burners can operate with up to 11 % ammonia, whereas 13.5 % ammonia is possible in low-pressure systems. The explosion limit also depends on the flow velocity (Table 2, see also [3]) and the water content of the reaction mixture [11].

Table 2. Explosion limits of ammonia – air mixtures at atmospheric pressure

Flow velocity, m/s	Lower explosion limit, % NH_3	Upper explosion limit, % NH_3
0	15.5	27.5
3	28	38
5 – 8	30	40
12	32	37
14	none	none

According to Le Chatelier's principle, the increase in volume in Equation (4) implies that conversion declines as pressure rises (Fig. 4, see next page).

If the gas velocities are too high or the number of catalyst gauzes is insufficient, conversion to

nitrogen monoxide decreases because of the slip (leakage) of ammonia which reacts with it according to Equation (8). If the gas velocities are too low or too many gauzes are used, decomposition of nitrogen monoxide according to Equation (7) is promoted. Table 3 gives typical gas velocities.

Figure 4. Conversion of ammonia to nitrogen monoxide on a platinum gauze as a funtion of temperature [5]
a) 100 kPa; b) 400 kPa

Table 3. Typical design data for ammonia burners

Pressure, MPa	Number of gauzes	Gas velocity, m/s	Reaction temperature, °C	Catalyst loss, g/t HNO_3
0.1 – 0.2	3 – 5	0.4 – 1.0	840 – 850	0.05 – 0.10
0.3 – 0.7	6 – 10	1 – 3	880 – 900	0.15 – 0.20
0.8 – 1.2	20 – 50	2 – 4	900 – 950	0.25 – 0.50

Figure 5. Losses of precious metals in the combustion of ammonia to nitrogen monoxide as a function of temperature and catalyst composition [5]
a) Pt; b) Pt – Rh 98/2; c) Pt – Rh 90/10

A high reaction temperature promotes ammonia combustion (Fig. 4), but high temperature decreases the conversion. Maximum temperatures up to 950 °C have been realized, but catalyst losses, chiefly due to vaporization, increase greatly (Fig. 5). The usual way to maintain the conversion toward the end of a campaign in spite of catalyst deactivation and losses, is to raise the temperature. The ammonia – air ratio is directly related to the reaction temperature: a 1 % increase in the proportion of ammonia increases the temperature by ca. 68 K. If the temperature is too low, conversion to nitrogen monoxide decreases. The reaction temperature also depends on the temperature of the inlet gas mixture. The following formula provides an approximate value in °C:

$$t_{\text{reactor}} = t_{\text{gas mixture}} + r \cdot 68$$
$$\text{where } r = \text{NH}_3 / (\text{NH}_3 + \text{air}) \quad (9)$$

Catalysts [12]. Since the introduction of the industrial production of nitric acid by the Ostwald process, several hundred materials have been tested as catalysts for ammonia combustion. Platinum catalysts have proved most suitable and are used almost exclusively today. Oxides of non-noble metals can also be employed; these cost less than platinum catalysts, but conversion is lower. Another disadvantage of non-noble-metal catalysts is that they are more quickly poisoned [13].

The usual form of catalyst is a fine-mesh gauze (standardized at 1024 mesh/cm^2). Manufacturers offer wire diameters of 0.060 and 0.076 mm. The Johnson Matthey "Tailored Pack" combines gauzes made of different wire diameters [14]. The upstream gauzes have a wire diameter of 0.076 mm and the downstream ones 0.060 mm to optimize the catalyst surface area.

High-pressure plants also utilize "fiber packs" in which a fraction of the fibrous catalyst material is held between two gauzes [15]. The packs have the advantage of reduced platinum loss and thus longer run times. " Fiber packs" have not yet been used in medium-pressure ammonia combustion because fewer gauzes are used in medium-pressure than in high-pressure processes (see Table 3), so the lower pressure drop results in poorer distribution.

To reduce catalyst consumption, particularly in gauzes at the bottom of the reactor, ceramic grids coated with platinum – rhodium have also been developed [16]. Platinum is usually alloyed with 5 – 10 % rhodium to improve its strength and to reduce catalyst loss. During combustion,

the metal surface becomes enriched in rhodium, thus improving catalytic activity [17]. Because rhodium is more expensive than platinum, a rhodium content of 5 – 10 % has proved optimal. Figure 6 shows the efficiency of conversion to nitrogen monoxide and the platinum loss as a function of the rhodium content of the alloy [18].

Figure 6. Conversion of ammonia to nitrogen monoxide on platinum gauze (a) and platinum losses (b) as a function of catalyst composition

If a low reaction temperature (< ca. 800 °C) is unavoidable, a pure platinum catalyst should be employed, because otherwise rhodium(III) oxide would accumulate at the catalyst surface and decrease catalytic activity [18]. Palladium is also used in catalyst alloys. Laboratory studies on the catalytic activity of 90 % Pt – 10 %Rh and 90 %Pt – 5 %Rh – 5 %Pd gauzes reveal no great differences in nitrogen monoxide yield [19]. The ternary catalyst is of economic interest because palladium costs much less than platinum or rhodium.

Platinum gauzes are pretreated by the manufacturer (Degussa and Heraeus, FRG; Johnson Matthey and Engelhard, UK) so that they do not need to be activated after installation in the burner. The reaction is ignited with a hydrogen flame until gauzes glow red. After the reaction has been initiated, crystal growth rapidly increases the surface area. The highest conversion on the catalyst is obtained after a few days use. Specially pretreated platinum gauzes that reach maximum activity after just a few hours are also on the market [20]. Start-up problems with platinum gauzes are discussed in [21]. The prolonged decline in activity after the conversion maximum is due to catalyst poisoning and platinum loss. Catalyst poisons include iron oxide (rust) and dust in the process air, which is especially concentrated in the vicinity of fertilizer plants. Any material deposited on the catalyst surface acts as a poison. A multistage filter is used to prevent these substances from reaching the catalyst (see Section 1.3.3.1).

Platinum loss during operation is caused by vaporization and abrasion. Vaporization loss predominates, but if heavy vaporization loss weakens the structure then abrasion can substantially lower burner efficiency. Platinum loss due to vaporization is thought to involve the formation of short-lived platinum dioxide:

$$Pt + O_2 \longrightarrow PtO_2(g)$$

Mechanical losses are accelerated by impurities in the reaction mixture, which can lead to the formation of whiskers at the grain boundaries. The whiskers are more easily broken off by the flowing gas.

Recovery of Precious Metals. Precious-metal losses from the catalyst have a significant effect on the operating costs of a nitric acid plant. The approximate losses and resulting costs can be determined from the ammonia combustion temperature and the loading. Losses increase with temperature and loading; however, smaller losses may be measured at higher loadings because a more uniform incoming flow causes less movement of the gauzes relative to one another and thus reduces mechanical losses. Table 3 lists typical loss rates. Platinum recovery systems are installed in most nitric acid plants to improve process economics.

Mechanical Filters. Mechanical filters are made of glass, mineral wool, or ceramic or asbestos fibers. They are normally installed where the gas temperature is < 400 °C. Their most important drawback is their large pressure drop, which can reach 25 kPa between filter changes.

Mechanical filters recover 10 – 20 % platinum, but recovery rates up to 50 % have been reported [22]. These filters have the advantage of low capital costs and the disadvantage of high operating costs resulting from the large pressure drop across the filter. For economic reasons, they are only employed in mono-high-pressure plants.

In low-pressure burners, marble chips 3–5 mm in length were used immediately downstream of the catalyst gauzes [23]. At high reaction temperature, the marble is converted to calcium oxide, whose high absorption capacity for platinum and rhodium permits up to 94 % recovery. During reactor shutdown, however, the calcium oxide must be protected against moisture.

Recovery Gauzes. A technically elegant approach to platinum recovery is to install, just downstream of the catalyst gauzes, a material that is stable at high temperature and that can absorb platinum oxide vapor and form an alloy with it. The first recovery gauzes in production plants (supplied by Degussa in 1968) consisted of a gold – palladium alloy (20/80). Nowadays most such gauzes are gold-free but have a low content of nickel (ca. 5 %) to enhance their strength. The gauzes have 100 – 1350 mesh/cm^2 and are made of wire with a diameter of 0.2 – 0.06 mm. Several recovery gauzes with different specifications are usually installed. Loss of platinum from the catalyst is greater than that of rhodium; for example, the calculated loss composition for a 90/10 Pt – Rh gauze is 95/5. A "recovery factor" can be determined for each recovery gauze, indicating how much of the available platinum is retained by the gauze. This recovery factor depends on the specifications of the gauze, the operating pressure, and the loading. Figure 7 shows the dependence of the recovery efficiency on wire diameter and mesh fineness [24]. A method for selecting the optimum platinum recovery gauze system for a particular nitric acid plant is described in [25].

The captured platinum diffuses into the palladium gauze and forms an alloy. The topmost gauze is often designed to reach saturation in one campaign, usually 180 d. Determining the economic optimum for a recovery system (the most important criterion is the weight of palladium required) necessitates taking into account the fact that palladium is lost. This loss corresponds to about one-third of platinum recovery.

"Getter" systems can recover more than 80 % of the platinum lost from the catalyst. The mechanism of rhodium recovery has not yet been fully elucidated. Up to 30 % of rhodium from the catalyst is captured by recovery systems.

Figure 7. Performance of a palladium-based recovery gauze as a function of mesh size and wire diameter

1.3.2. Oxidation and Absorption of Nitrogen Oxides

After the combustion of ammonia, the nitrogen monoxide product gas is cooled en route to absorption and, if necessary, compressed. As a result, part of the nitrogen monoxide is oxidized to nitrogen dioxide or dinitrogen tetroxide (Eq. 2), which is converted to nitric acid by absorption in water (Eq. 3).

Absorption is usually performed in plate columns where the nitrous gases are converted to nitric acid in the liquid phase on the plates. Nitrogen monoxide is constantly reformed in this step and prevents complete absorption of the inlet gases. Oxidation of nitrogen monoxide occurs mainly in the gas phases between the plates, but also in the gas phase of the bubble layer on them.

Gas Phase. The gas phase is the site of nitrogen monoxide oxidation

$$2\,NO + O_2 \longrightarrow 2\,NO_2 \quad \Delta H = -1127\,\text{kJ/mol} \qquad (10)$$

as well as nitrogen dioxide dimerization

$$2\,NO_2 \rightleftharpoons N_2O_4 \;\; \Delta H = -58.08\,\text{kJ/mol} \tag{11}$$

and dinitrogen trioxide formation

$$NO + NO_2 \rightleftharpoons N_2O_3 \;\; \Delta H = -40\,\text{kJ/mol} \tag{12}$$

Reaction of the oxidized nitrogen oxides with water vapor leads to formation of nitrous and nitric acids. These reactions are of secondary importance from an engineering standpoint.

To describe the kinetics of nitrogen monoxide oxidation (Eq. 10), a third-order rate equation is used [26]:

$$r = \frac{k_p}{RT} p_{NO}^2 p_{O2} \tag{13}$$

where

r	= reaction rate, kmol m^{-3} s^{-1}
k_p	= reaction rate constant, atm^{-2} s^{-1}
R	= universal gas constant, m^3 atm kmol^{-1} K^{-1}
T	= temperature, K
p	= partial pressure, atm

The rate constant is defined by

$$\log k_p = \frac{652.1}{T} - 1.0366 \tag{14}$$

This reaction is unusual because it goes to the right faster at low temperature than at high temperature, i.e., the reaction rate has a negative temperature coefficient.

Because equilibrium in the nitrogen dioxide dimerization system is reached very quickly, an equilibrium formula

$$r = \frac{k_p}{RT}\left(p_{NO2}^2 - \frac{p_{N2O4}}{K_p}\right) \tag{15}$$

can be assumed where K_p is the equilibrium constant. The dimerization rate is virtually independent of temperature [27], so the rate constant at 25 °C

$$k_p = 5.7 \times 10^5\,\text{atm}^{-1}\text{s}^{-1} \tag{16}$$

can be used at all temperatures of technical interest.

Hoftyzer and Kwanten [28] give the following equation for the $NO_2 - N_2O_4$ equilibrium constant:

$$K_p = \frac{p_{N2O4}}{p_{NO2}^2} = 0.698 \times 10^{-9} \exp\left(\frac{6866}{T}\right) \tag{17}$$

An equilibrium formula can also be written for dinitrogen trioxide formation:

$$r = \frac{k_p}{RT}\left(p_{NO}\,p_{NO2} - \frac{p_{N2O3}}{K_p}\right) \tag{18}$$

According to [27], the equilibrium constant can be determined as

$$K_p == \frac{p_{N2O3}}{p_{NO}\,p_{NO2}} = 65.3 \times 10^{-9} \exp\left(\frac{4740}{T}\right) \tag{19}$$

Liquid Phase. The large number of reactive components in the gas phase (NO, NO_2, N_2O_3, N_2O_4) means that the reaction model for absorption is complicated. Figure 8 (see next page) shows a sophisticated model devised by Hoftyzer and Kwanten [28].

The main route for the formation of nitric acid in this model involves two steps in the liquid phase. First, dissolved dinitrogen tetroxide reacts with water, yielding nitric and nitrous acids:

$$N_2O_4 + H_2O \longrightarrow HNO_3 + HNO_2 \quad \Delta H = -87.0\,\text{kJ/mol} \tag{20}$$

Nitrous acid then dissociates to nitric acid, water, and nitrogen monoxide, the latter being transported across the interface into the bulk gas:

$$3\,HNO_2 \longrightarrow HNO_3 + H_2O + 2\,NO \quad \Delta H = -15.3\,\text{kJ/mol} \tag{21}$$

According to Andrew and Hanson [29], a first-order equation can be written for the rate of dinitrogen tetroxide hydrolysis:

$$r = k\,c_{N2O4} \tag{22}$$

where $c_{N_2O_4}$ is the concentration of dinitrogen tetroxide in kmol/m^3. The rate constant is given by

$$\log k = -\frac{4139}{T} + 16.3415 \tag{23}$$

The kinetics of nitrous acid dissociation were studied by Abel and Schmid [30], with the following result:

$$r = k\,\frac{c_{HNO2}^4}{p_{NO}^2} = \frac{k}{H_{NO}^2}\,\frac{c_{HNO2}^4}{c_{NO}^2} \tag{24}$$

Figure 8. Nonstoichiometric model of absorption of nitrogen oxides in water [28]

where H_{NO} is the Henry coefficient for nitrogen monoxide in m^3atm/kmol and c ist the concentration in kmol/m^3. The rate constant is defined by

$$\log k = -\frac{6200}{T} + 20.1979 \tag{25}$$

Equations (23) and (25) were derived by Hoffmann and Emig [31] and are based on experimental data from [32].

Mass Transfer. For more than 50 years scientists have studied the transport of nitrogen oxides in water and in dilute and concentrated nitric acid. A variety of mechanisms have been proposed depending on the gas composition and the acid concentration. These are partly in agreement with the absorption model of Figure 8.

In the NO_x absorption region important for acid formation, dinitrogen tetroxide transport is considered to be the rate-limiting step. The quantity of dinitrogen tetroxide transported from the bulk gas to the interface depends chiefly on the $NO_2 - N_2O_4$ equilibrium [28, 33]:

$$J_{N2O_4} = \frac{k_{gNO2}}{2RT}\left(p^{o}_{NO2} - p^{i}_{NO2}\right) + \frac{k_{gN2O_4}}{RT}\left(p^{o}_{N2O_4} - p^{i}_{N2O_4}\right) \tag{26}$$

where

J = absorption rate, kmol m^{-2} s^{-1}
k_g = gas-side mass-transfer coefficient, m/s
p^o = partial pressure in the bulk gas, atm
p^i = partial pressure at the interface, atm

At higher NO_2 /N_2O_4 concentrations in the reaction gas, primarily dinitrogen tetroxide crosses the interface and reacts in the fast first-order reaction (Eq. 20) to form nitric and nitrous acids. Nitrous acid dissociates (Eq. 21), and the resulting nitrogen monoxide is transported back into the gas space.

The following equation can be written for the absorption rate of dinitrogen tetroxide [34]:

$$J_{N2O_4} = H_{N2O_4} p_{N2O_4} \sqrt{k D_{N2O_4}} \tag{27}$$

where

H = Henry coefficient, m^3 atm/kmol
k = rate constant, s^{-1}
D = diffusion constant, m^2 /s

Numerous measurements in laboratory absorbers support this mechanism. Interpretations of measurements in absorption columns have given the following correlations for the mass-transfer coefficients [35]:

1) Bubble-cap trays

$$H_{N_2O_4}\sqrt{k\,D_{N_2O_4}} = \exp\left(-\frac{1500}{T} - 4.3790 - 23.279\,W_{HNO_3} + 130.42\,W^2_{HNO_3} - 370.87\,W^3_{HNO_3} + 486.94\,W^4_{HNO_3} - 236.54\,W^5_{HNO_3}\right) \text{ kmol m}^{-2}\text{ kPa}^{-1}\text{ s}^{-1} \tag{28}$$

2) Sieve trays

For $W_{HNO_3} > 0.05$

$$H_{N_2O_4}\sqrt{k\,D_{N_2O_4}} = \exp\left(-\frac{1500}{T} - 2.7648 - 39.614\,W_{HNO_3} + 181.98\,W^2_{HNO_3} - 429.65\,W^3_{HNO_3} + 496.99\,W^4_{HNO_3} - 223.24\,W^5_{HNO_3}\right) \quad \text{kmol m}^{-2}\,\text{kPa}^{-1}\,\text{s}^{-1} \tag{29a}$$

For $W_{HNO_3} < 0.05$

$$H_{N_2O_4}\sqrt{k\,D_{N_2O_4}} = \exp\left(-\frac{1500}{T} + 0.2548 - 315.73\,W_{HNO_3} + 9256.2\,W^2_{HNO_3} - 95.602\,W^3_{HNO_3}\right) \quad \text{kmol m}^{-2}\,\text{kPa}^{-1}\,\text{s}^{-1} \tag{29b}$$

where

H = Henry coefficient, m^3kPa/kmol
T = temperature, K
W = mass fraction

The absorption of $NO_2 - N_2O_4$ in concentrated nitric acid can be treated as pure physical absorption [36]. Deviations from the described chemisorption also occur at low gas-phase $NO_2 - N_2O_4$ concentrations [29].

Absorption Equilibrium. Equilibrium considerations allow determination of the maximum possible acid concentration for a given composition of the inlet gas. For example, suppose the overall reaction is

$$3\,NO_2\,(g) + H_2O\,(l) \rightleftharpoons 2HNO_3(l) + NO\,(g)$$
$$\Delta H = -72.8\,\text{kJ/mol} \tag{30}$$

and the equilibrium constant is defined as

$$K_p = \frac{p^2_{HNO3}\,p_{NO}}{p^3_{NO2}\,p_{H2O}} \tag{31}$$

with the partial pressures of nitrogen monoxide (p_{NO}) and nitrogen dioxide (p_{NO_2}) in the gas phase and the vapor pressures of nitric acid (p_{HNO_3}) and water (p_{H_2O}) over the dilute acid. In industrial absorption the equilibrium constant depends only on temperature. The equilibrium constant is conventionally split into two terms:

$$K_p = K_1 \cdot K_2$$
$$\text{where}\, K_1 = \frac{p_{NO}}{p^3_{NO2}} \text{ and } K_2 = \frac{p^2_{HNO3}}{p_{H2O}} \tag{32}$$

K_2 depends on the acid concentration and the temperature. Gases (N_2O_4, N_2O_3, HNO_2) dissolved in the dilute acid affect the activities of

Figure 9. Vapor pressures of nitric acid and water as a function of acid strength and temperature [28]
1mm Hg = 133.2 mPa

Figure 10. Value of K_1 from Equation (32) as a function of acid concentration and temperature [28]

nitric acid and water. Up to a nitric acid concentration of 65 wt % and an inlet nitrogen oxide partial pressure of 100 kPa, however, the vapor pressures from the binary system $HNO_3 - H_2O$ can be used to determine K_2 (Fig. 9).

Figure 10 shows how K_1 depends on the acid concentration and the temperature. This parameter is particularly interesting from an engineering standpoint because it allows the acid strength to be determined if the gas concentration is known.

If the equilibrium is based on the overall reaction

$$3/2\ N_2O_4(g) + H_2O(l) \rightleftharpoons 2\ HNO_3(l) + NO_3\ (g) \qquad \Delta H = -75\ \text{kJ/mol} \tag{33}$$

the equilibrium constant is

$$K_p = K_1 \cdot K_2 \quad \text{where } K_1 = \frac{p_{NO}}{p_{N_2O_4}^{3/2}} \text{ and } K_2 = \frac{p_{HNO_3}^2}{p_{H_2O}} \tag{34}$$

Again Figure 9 gives the K_2 values. In this formulation, K_1 is a function of the acid concentration and does not depend on temperature (Fig. 11). The curve of Figure 11 can be fitted by an empirical equation [37]:

$$\log K_1 = 7.412 - 20.29 W_{HNO_3} + 32.47 W_{HNO_3}^2 - 30.87 W_{HNO_3}^3 \tag{35}$$

where W denotes the mass fraction.

Figure 11. Value of K_1 from Equation (34) as a function of acid concentration

Another way of describing the absorption equilibrium is to start with the hypothetical component NO_2 denoted as "chemical NO_2":

$$p_{\tilde{NO}_2} = p_{NO_2} + 2p_{N_2O_4} \tag{36}$$

The nitrogen dioxides, considered as completely dissociated, are assumed to react according to

$$3\ \tilde{NO}_2(g) + H_2O(l) \rightleftharpoons 2\ HNO_3(l) + NO(g) \tag{37}$$

This hypothetical reaction leads to the equilibrium relation

$$K_p = K_1 \cdot K_2 \quad \text{where } K_1 = \frac{p_{NO}}{p_{\tilde{NO}_2}^3} \text{ and } K_2 = \frac{p_{HNO_3}^2}{p_{H_2O}} \tag{38}$$

The equilibrium constant K_p can be estimated with the following equation [38]:

$$\log K_p = -7.35 + \frac{2.64}{T} \tag{39}$$

Then K_1 can be determined from K_p, and the K_2 values obtained from Figure 9. The parameter K_1 determines the equilibrium curves for constant temperature and constant acid concentration when p_{NO_2} is plotted against p_{NO} (Fig. 12). The K_1 values are necessary to calculate the absorption of nitrous gases according to Toniolo [39]. The application of the Toniolo diagram is described in [40].

Modeling of the Absorption Tower. The literature offers many methods for calculating the absorption of nitrous gases; they can be classified according to the number of reactions, the reaction kinetics, or the type of mathematical method:

1) *Number of Reactions*. The simplest calculation model uses Equation (30) to describe the events on an absorption plate and a kinetic formula to describe nitrogen monoxide oxidation between two oxidation plates [41]. Extended models [42–45] also take into account the dimerization of nitrogen dioxide to dinitrogen tetroxide. In this way it is possible to describe nitric acid formation not just via nitrogen dioxide but also via dinitrogen tetroxide [46–49].
   Models that include the formation and dissociation of nitrous acid in the liquid phase give the best description of known chemical events [31, 50]. A model that permits nitrous acid formation in the gas phase has also been proposed [51].

Figure 12. Toniolo diagram for an absorption tower [39]
A → B absorption process; B → C oxidation process

2) *Reaction Kinetics*. Most design computations use equilibrium equations for the basic reactions. These static methods have the drawback of requiring the introduction of efficiency factors [51] that take into account limitation of transport of the reactants across the interface. Dynamic methods do not need empirical efficiency factors because they describe mass transfer in terms of physical and chemical laws [28,31,50,52].
3) *Mathematical Methods*. In view of the large number of nonlinear equations to be solved in both equilibrium and dynamic models, plate-to-plate calculations are generally described in the literature. The relaxation method [31] and a special stage-to-stage calculation [52], however, have also been used for the design of absorption towers.

By way of example, an equilibrium model and a transport model are described in more detail.

Equilibrium Model.

The equilibrium model is based on Equations (11) and (33). If a gas of known composition is fed to the plate and an acid of known strength leaves the plate, the calculation begins at the bottom of the tower. If the gas throughput is taken to be constant (because of the high content of inerts), the following mass balance is obtained for the n-th plate:

$$3\left(y_{n,\mathrm{NO}} - y_{n-1,\mathrm{NO}}\right) = \left(y_{n-1,\mathrm{NO_2}} + 2y_{n-1,\mathrm{N_2O_4}}\right) - \left(y_{n,\mathrm{NO_2}} + 2y_{n,\mathrm{N_2O_4}}\right) \tag{40}$$

where y is the mole fraction in the vapor phase.

Equilibrium Equations (34) for K_{p^1} and (17) for K_{p^2} give the equation

$$\begin{aligned} &a y_{n,\mathrm{NO_2}}^3 + b y_{n,\mathrm{NO_2}}^2 + y_{n,\mathrm{NO_2}} + d = 0 \\ &\text{with } a = 3\left(K_{p_1}\sqrt{p}\right)\left(K_{p_2} p\right)^{1.5} \\ &b = 2\left(K_{p_2} p\right) \\ &d = -\left(3y_{n-1,\mathrm{NO}} + y_{n-1,\mathrm{NO_2}} + 2y_{n-1,\mathrm{N_2O_4}}\right) \end{aligned} \tag{41}$$

This formula allows the compositions of the gas leaving the n-th plate and the acid arriving at the n-th plate to be determined.

Before the $(n+1)$-th plate is calculated, the oxidation of nitrogen monoxide must be determined. The flow behavior of the nitrous gases in an absorption tower is not known exactly, so the oxidation space can be described as either a tubular or a stirred-tank reactor. Actual conditions probably lie somewhere between the two [28], but trends can be identified on the basis of plate type. The stirred-tank model is preferred for bubble-cap trays [47], but flow-through conditions can be expected in the case of sieve plates. Because virtually all absorption towers today are fitted with sieve plates, only these are discussed.

When the reaction is carried out isothermally, integration of the rate equation

$$-\frac{\mathrm{d}p_{\mathrm{NO}}}{\mathrm{d}t} = k p_{\mathrm{NO}}^2 p_{\mathrm{O2}} \tag{42}$$

gives a solution

$$\theta = \frac{2}{k\left(2p_{\mathrm{O2}} - p_{\mathrm{NO}}\right)} \cdot \left\{\frac{x}{p_{\mathrm{NO}}(1-x)} - \frac{1}{2p_{\mathrm{O2}} - p_{\mathrm{NO}}} \ln\left[\frac{2p_{\mathrm{O2}} - p_{\mathrm{NO}}x}{2p_{\mathrm{O2}}(1-x)}\right]\right\} \tag{43}$$

where

θ = residence time, s
k = rate constant, $atm^{-2}\,s^{-1}$
p = partial pressure, atm
t = time, s
x = fraction of oxidized nitrogen monoxide

in which x must be determined by iteration from the residence time θ and the inlet partial pressures of nitrogen monoxide (p_{NO}) and oxygen (p_{O_2}) [47]. The partial pressures of the other components leaving the reactor can be calculated from the fraction x of oxidized nitrogen monoxide.

If an excess of oxygen is assumed to be present, the rate equation can be simplified [53] as

$$-\frac{dp_{NO}}{dt}=\bar{k}p_{NO}^2 \tag{44}$$

so that the partial pressure of nitrogen monoxide at the reactor outlet (p'_{NO}) can be determined:

$$\frac{1}{p'_{NO}}=\frac{1}{p_{NO}}+(2p_{O2}-p_{NO})\frac{k\theta}{2} \tag{45}$$

Because the oxidation reaction is highly exothermic, the tubular reactor can be designed for isothermal operation only when conversion is very low (e.g., when the tail gas contains little NO). Otherwise, adiabatic reaction conditions must be assumed. To describe the reaction under adiabatic conditions the oxidation space is divided into n layers, in each of which the reaction is isothermal. The temperature increase from one layer to the next is given by [33]

$$\Delta T=1/2\frac{C_{NO,0}\,(-\Delta H_R)}{\varrho_0\bar{C}_p}\frac{G_{NO,0}-G_{NO}}{G_{NO,0}} \tag{46}$$

where

$C_{NO,0}$ = initial concentration of NO, $kmol/m^3$
$\bar{C}_p$ = molar heat capacity, $kJ\,kmol^{-1}\,K^{-1}$
G_{NO} = molar gas flow rate, kmol/s
$G_{NO,0}$ = initial gas flow rate, kmol/s
ΔH_R = reaction enthalpy, kJ/kmol
ϱ_0 = initial density, kg/m^3

Transport Model. A transport model for the absorption tower is based on a series of units, each containing a bubble- column reactor and an adiabatic plug flow reactor (Fig. 13) [52]. The bubble-column reactor, modeled as two ideal stirred-tank reactors, simulates the liquid with gas bubbles on a tray (absorption space). The adiabatic plug flow reactor simulates oxidation between plates (oxidation space).

Figure 13. Hydrodynamic model of absorption tower
g = molar gas flow rate of a component; G = molar flow rate of gas; L = molar flow rate of liquid; p = pressure; T = temperature; T_{cw} = temperature of cooling water; V = volume; x = mole fraction in liquid phase; y = mole fraction in gas phase

The balances are carried out with the equations

$$G_n y_{n,i}-G_{n-1}y_{n-1,i}-k_{g,i}aV\frac{p_n}{RT_n}\left(y^*_{n,i}-y_{n,i}\right)=V_g\sum_{j=1}^{M_g}\nu_{g,ij}r_{g,j} \tag{47}$$

$i = N_2,\ O_2,\ NO,\ NO_2,\ N_2O_4$ and $\sum_{i=1}^{k} y_{n,i}=1$ for the components in the gas phase (subscript g) where

a = interfacial area per unit volume, m^2/m^3
G = molar gas flow rate, kmol/s
k_g = gas-side mass-transfer coefficient
M_g = number of reactions in the gas phase
n = plate number
r = reaction rate, $kmol\,m^{-3}\,s^{-1}$
V = volume of bubble layer
V_g = volume of gas phase in bubble layer
y_i = mole fraction of i-th component in liquid phase

Figure 14. Equipment needed in a nitric acid plant

$y*_i$ = mole fraction of i-th component in liquid phase at the phase boundary
ν = stoichiometric coefficient

Analogously for the liquid phase (subscript l)

$$L_n x_{n,i} - L_{n+1} x_{n+1,i} + k_{l,i} a V c_n \left(x^*_{n,i} - x_{n,i}\right) \pm \tilde{L}_n \tilde{x}_{n,i} = V_l \sum_{j=1}^{M_l} \nu_{l,ij} r_{l,j} \quad (48)$$

i = NO, N_2O_4, HNO_2, HNO_3, H_2O and $\sum_{i=1}^{k} x_{n,i} = 1$
where

c = molar concentration, kmol/m^3
L = molar liquid flow rate, kmol/s
x = mole fraction in liquid phase
$\tilde{L}$ = side stream
M_l = number of reactions in the liquid phase

Thermodynamic equilibrium is assumed at the interface,

$$y^*_{n,i} = H_{n,i} x^*_{n,i} \quad (49)$$

where H is the Henry coefficient and the formula

$$k_{g,i} \frac{p_n}{RT_n} \left(y_{n,i} - y^*_{n,i}\right) = k_{l,i} c_n \left(x^*_{n,i} - x_{n,i}\right) \quad i = \mathrm{NO}, \mathrm{N_2O_4} \quad (50)$$

is used for dynamic mass transfer between phases. A separate heat balance is performed for each phase, so that the temperature may differ in both phases of a single stage. The mathematical treatment of this model is described in [52].

1.3.3. Equipment

Figure 14 summarizes the equipment needed to implement the three chemical steps involved in nitric acid production (Fig. 2). In addition to producing nitric acid, a nitric acid plant also generates steam or mechanical energy from the chemical energy liberated.

1.3.3.1. Filters and Mixers

To obtain the highest possible conversion of ammonia on the catalyst and a long catalyst life, the starting materials (air and ammonia) must be purified. The air must be very clean to prevent catalyst poisoning (page 6).

Air Filter. A multistage filter is normally used on the air intake to a nitric acid plant and should remove 99.9 % of all particles larger than 0.5 µm.

Typical filter media are plastic and glass fibers. Filter frames should be made of stainless steel. Air filters must be replaced regularly because filter bags can tear or filter mats can be-

come overloaded and cause an excessive pressure drop. Filter life depends on the particulate load in the air (typically 0.8 mg/m^3). In areas where sandstorms may occur (maximum loading 500 mg/m^3), the use of a sand separator (a centrifugal collector) as a prefilter is recommended.

Ammonia Filters. The liquid ammonia filter removes solid contaminants, especially small rust particles; 99.9 % of all particles larger than 3 µm should be eliminated. Selection of a liquid ammonia filter requires consideration of the fact that traces of oils and chlorides are also present in ammonia. Proven filter materials are Teflon and sintered metals. Polypropylene and ceramic filter candles (cartridges) are also employed. Magnetic filters have found some use but have limited capacity.

Filtration of ammonia gas should remove 99.9 % of oil and solid particles larger than 0.5 µm. The principal filter media are glass fibers, sintered metals, and ceramics. The pressure drop is up to 10 kPa, depending on filter type.

Filters for the Mixed Gas. The mixed-gas filter provides final cleaning of the ammonia–air mixture and improves the mixing of the air and ammonia; it should remove 99.8 % of all particles larger than 1.5 µm. Contaminants in the gas mixture not only originate externally (in the process air and ammonia) but are also formed by corrosion inside the system (rust). The gas mixture filter should therefore be installed as near as possible to the burner. Ceramic filter cartridges are generally used in which silicon dioxide is the dominant constituent. For a filter cartridge with a surface loading of 250 m^3/m^2, the maximum pressure drop in the clean state is 10 kPa.

Mixers. Static gas mixers are used for two purposes in nitric acid plants:

1) To mix ammonia and air in a ratio of ca. 1 : 10 for catalytic oxidation (see Section 1.3.1)
2) To mix ammonia and tail gas in a ratio of 1 : 100 for the catalytic reduction of NO_x as part of tail-gas treatment (see Section 1.4.2.3).

From an economic standpoint, homogeneous mixing of the gas streams upstream of the reactor is important in both cases. Local ammonia excesses in the burner are a risk for plant safety (explosion limit) and may also cause overheating of the catalyst gauze. Poor mixing lowers the conversion of ammonia to nitrogen monoxide and increases platinum loss from the catalyst.

The efficiency of a given mixing operation is described by the standard deviation σ of measured samples from the theoretical value $\bar{x}$ a certain distance downstream from mixing. In nitric acid plants, the deviation should be < 1 %. If the theoretical ammonia concentration in a mixture is 10 %, for example, measured values fluctuate between 9.9 and 10.1 % [54]. Only static mixers are used (e.g., the Uhde tubular mixer or the Sulzer three-element mixer).

1.3.3.2. Burners and Waste-Heat Boilers

Figure 15. Reactor for catalytic ammonia oxidation with waste-heat recovery system (Lentjes)
a) Burner head; b) Perforated plate; c) Platinum gauzes and platinum recovery gauzes; d) Inspection glass; e) Superheater and evaporator tubes; f) Hydrogen ignition; g) Refractory packing; h) Nitrous gas outlet

Figure 16. Water and steam connections of heat exchangers (Lentjes) downstream of catalysis
a) Reactor; b) Economizer; c) Steam drum; d) Boiler feedwater pumps; e) Preevaporator; f) Upper superheater; g) Lower superheater; h) Main evaporator

The heat of reaction liberated during ammonia combustion is utilized to produce steam and preheat the tail gas. Steam is produced in a waste-heat boiler located immediately below the burner (Fig. 15). The burner consists of a burner basket packed with filling material to ensure uniform distrubution of the downward flowing reaction gas. Platinum recovery gauzes (page 7) are located above the filling material. The catalyst gauzes (page 6) are located above the recovery gauzes. The burner basket is clamped between the flanges of the burner head and the waste-heat boiler. To ensure better distribution of the reaction mixture, the burner head also contains a perforated plate or honeycomb grid. Hydrogen burners rotating above the surface are often used for ignition. The gauze temperature is measured, and the space above the gauze can be observed through inspection glasses. The gauzes glow bright red during catalysis. The throughput per element can produce up to 1200 t of 100 % nitric acid per day.

Waste-heat boilers up to 6 m in diameter are used. Figure 15 shows a waste-heat boiler for medium-pressure burning. The preevaporator is located directly below the burner basket and protects the downstream superheater against excessive temperature. The superheater is followed by the main evaporator. Evaporator tubes are also installed at the wall to cool it and protect it from excessive temperature.

Figure 16 shows how heat from the waste-heat boiler is used to raise steam. Boiler feedwater is led through the economizer (b) into a steam drum (c). Water at thermal equilibrium with the steam is pumped from the drum through the evaporators. Steam from the drum goes first to the lower superheater (g) and is then cooled in the drum so that the desired temperature can be attained in the upper superheater (f).

Systems with an economizer integrated in the waste-heat boiler have also proved serviceable (Fig. 17, see next page). Here, as in the waste-heat boiler of Figure 15, the heat-exchanger tubes can be arranged spirally in disk form or in a square pack.

A shell-and-tube evaporator with natural circulation can also be used (Fig. 18, see next page). The superheater tubes (e) are again arranged as a flat spiral. These waste-heat boilers are particularly suitable for smaller plants or those using low steam pressure.

Stress cracking corrosion is a special threat to economizer tubes. Start-up always leads to the formation of ammonium salts; nitrous and nitric acids may also condense. To prevent very rapid corrosive attack, the equipment is therefore heated before start-up and the feedwater is preheated to a high temperature.

Waste-heat boilers can be designed for pressures up to 10 MPa and temperatures up to 550 °C in the superheater. The steam is used to drive a turbine or is exported.

1.3.3.3. Compressors and Turbines

Machines on a common shaft are used to deliver and compress the gases and supply the drive power needed for this purpose. Power sources are the tail-gas turbine and a steam turbine or electric motor. The tail-gas turbine can supply 35 – 100 % of the compression energy required for the process, depending on the degree of preheating; the remainder comes from the steam turbine. The machinery used depends on the nitric acid process and may consist of an air compressor, a nitrous gas compressor, a tail-gas turbine, and a steam turbine or an electric motor.

Figure 19 shows the nitric acid process with atmospheric combustion and medium-pressure (400 – 600 kPa) absorption. The nitrous gas compressor (b) sucks the reaction mixture through the burner and simultaneously provides the pressure needed for absorption. This compressor does not have interstage cooling and can be of radial or axial design. The tail gas from the absorption column is expanded in a tail-gas turbine (d), usually a single-stage device. The rest of the power required to drive the nitrous gas compressor is supplied by the steam turbine or an electric motor.

Figure 20. Flow sheet of a nitric acid process with medium-pressure combustion and medium-pressure absorption
a) Air compressor; b) Reactor with waste-heat recovery system; c) Absorption tower; d) Tail-gas turbine; e) Steam turbine; f) Heat exchanger network

Figure 20 shows a medium-pressure process (400 – 600 kPa), as preferred for small- or medium- capacity plants ($\leq$ 600 t/d 100 % HNO_3). The machinery for this process includes a radial or axial air compressor (a) without interstage cooling, a single-stage tail-gas turbine (d), and a steam turbine (e) or electric motor.

A dual-pressure process with medium-pressure combustion and high-pressure absorption calls for both an air compressor and nitrous gas compressor (Fig. 21). The air for combustion is delivered at 400 – 600 kPa by an uncooled radial or axial air compressor (a). The radial nitrous gas compressor (c) produces the 1.0 – 1.2 MPa pressure needed for absorption. The drive power for these two devices comes from a multistage tail-gas turbine (e) and a steam turbine (f) or electric motor. These systems are preferred for large- capacity plants ($\geq$ 400 t/d 100 % HNO_3), especially in Europe.

High-pressure plants (Fig. 22) are preferred in the United States because of lower investment costs. The machinery includes an air compressor with interstage cooling. Radial devices are generally used, but the low-pressure section in larger machines may be axial. The tail-gas turbine is usually a multistage reaction machine.

The *nitrous gas compressors* are virtually always of radial design, but axial machines are available. The design and operation of the com-

pressors must take particular account of the following properties of the gas stream:

1) Nitrites and nitrates may be formed
2) The nitrous gas is toxic and highly corrosive
3) Chemical reactions take place when nitrous gas is compressed

When the nitric acid plant is started up or in continuous operation, unreacted ammonia is present in the burner exit gas. The level in continuous operation is ca. 30 ppm of ammonia. As a result, nitrates and nitrites would accumulate in the nitrous gas compressor if they were not removed regularly. If the temperature exceeds 240 °C, combustion or explosion is possible. To avoid an explosion, water or steam is briefly sprayed into the suction of the nitrous gas compressor every 8 h [55]. Because nitrous gas is highly toxic, it must not be allowed to escape from the compressor. The machine is therefore equipped with air-purged labyrinth seals. Chemical reactions must be considered in the design of nitrous gas compressors. The endothermic dissociation of dinitrogen tetroxide to nitrogen dioxide removes heat from the stream [56] and can cool the gas by 20 °C or more.

Because of their large capacities, modern nitric acid plants usually employ axial *air compressors*. The possibility of surging in the compressor, especially during plant start-up, requires the installation of appropriate surge protection. Adjustable inlet guide vanes allow operation at various plant capacities.

Tail-gas turbines can be single-stage or multistage devices of axial or radial design. For part-

Figure 23. Ammonia evaporator
a) Evaporator tubes; b) Sparger; c) Drop separator

load operation, these machines are equipped with a group of valve-controlled nozzles or adjustable guide vanes in the inlet.

Steam turbines may be condensing or back-pressure machines with or without an extraction/side stream.

1.3.3.4. Heat Exchangers and Columns

Heat Exchangers. The shell-and-tube design predominates for tail-gas heat exchangers, with hot nitrous gas on the tube side and cool tail gas on the shell side. The pressure drop should be kept as low as possible to secure a favorable energy balance for the plant as a whole.

Ammonia Evaporator. Various types of equipment can be used for ammonia evaporation. Figure 23 shows a shell-and-tube heat exchanger with mist collector. Cooling water on the tube side is cooled on evaporation. In medium-pressure plants, the heat of vaporization is also taken from chilled water used as coolant in the absorption step. The shell-side heat-transfer coefficients for ammonia can be calculated according to [57].

Gas Cooler – Condenser. In the cooler – condenser, the temperature is lowered below the dew point of the inlet nitrous gas. The nitric acid condensate has a concentration of, for example, ca. 40 wt % at medium pressure. Suitable materials of construction are discussed in Section 1.3.3.5. The thermal design of a gas cooler – condenser is difficult because the cooling step involves chemical reactions in both the gas and the condensed liquid phases. In the apparatus shown in Figure 24, nitrous gas passes into the shell side through two inlets; each of the partial streams reverses direction four times. Heat is absorbed by cooling water.

Absorption Tower. Absorption tower design is governed by the calculations for the oxidation process (i.e., tower height, see also Section 1.3.2) and thermal design. Because oxidation proceeds more slowly as the NO_x content in the tower decreases, the spacing between plates increases. Figure 25 shows an absorption tower for a plant with a daily production capacity of 1830 t of 100 % nitric acid. Acid formation takes place chiefly in the bottom third of the tower, whereas NO_x is reduced in the upper two-thirds. As a result, most of the heat must be withdrawn in the lower third; this is done with cooling coils on the plates. The coils on the upper plates primarily cool the nitrogen monoxide gas against chilled water, because oxidation proceeds faster at lower temperature. Most modern absorption towers have sieve plates. Compartments built into the bottom of the tower separate acid of medium strength from weak acid in case of plant

Figure 24. Cooler – condenser with feedwater preheaters attached to nitrous gas inlets

Figure 25. Absorption tower
a) Nitrous gas inlet; b) Inner compartment; c) Outer compartment

shutdown. The collected acids are pumped back to the tower at restart so that a steady state is reached more quickly. Before the tail gas leaves the tower, entrained acid droplets are collected in the demister.

Bleacher. The NO_x gases contained in the acid are stripped out with secondary air in the bleacher. A distribution tray delivers the acid evenly onto the Raschig ring packing. The packing rings are made of stainless steel, material no. 1.4301 (AISI 304) or 1.4306 (AISI 304L).

1.3.3.5. Construction Materials

Because of the special behavior of nitric acid toward metals (see Section 1.2), materials of construction for nitric acid plants must be selected very carefully. When industrial production began, acid-resistant masonry linings were used for plant components that came in contact with the product. By the 1920s, materials technology had advanced to the point that high chromium contents could be incorporated into alloy steels. Today, the principal materials of construction in nitric acid plants ($< 70\,\%$ HNO_3) are austenitic chromium – nickel steels containing 18 % chromium and 10 % nickel. The corrosion resistance

of these steels decreases with increasing temperature. Normal austenitic steels are generally not stable above 70 %. The chromium content determines the corrosion resistance; its anticorrosive action is influenced by the carbon content of steel. The chromium in the alloy forms a carbide (Cr_3C_2) at the grain boundaries; only small amounts of free chromium remain at high carbon contents, and the steel is therefore less corrosion resistant. If excess chromium remains after the amount needed for carbide formation is consumed, only this excess is responsible for the anticorrosion properties.

Figure 26. Anodic polarization curve for stainless steel Cr denotes the effect of chromium on the anodic polarization rate

The effect of chromium on the corrosion rate is shown in the anodic polarization curve of Figure 26. When chromium is present in the alloy, the passive region E_p (see Section 1.2) is reached sooner. Furthermore, chromium lowers the corrosion rate in the passive state and raises the transpassive potential E_{tr}. The last point is important because the corrosion potential of stainless steel in strong (highly concentrated) nitric acid often reaches the limit of the transpassive potential. In the transpassive range the passive layer starts to dissolve. A steel with too little chromium or with elements that lower the transpassive potential tends to corrode at a high rate [58].

Steels of a given specification behave differently under nitric acid attack because of permitted batch-to-batch variations in composition. The only way to be sure that a selected steel is suitable for an apparatus in contact with nitric acid is to perform tests. The best known method is the Huey test, in which a clean, polished piece of steel is immersed in boiling 65 % nitric acid at ambient pressure [59]. The specimen is exposed to these conditions for five successive 48-h periods, the acid being renewed at the beginning of each test period. The Huey test gives a good indication of how individual alloy constituents affect intergranular corrosion.

To ensure good weldability, the carbon content is limited to 0.03 %; alternatively, titanium or niobium is added as a stabilizer.

The stainless steels generally used in nitric acid plants are those classified unter material no. 1.4306 (AISI 304L); in the Federal Republic of Germany, however, the corresponding stabilized qualities, material no. 1.4541 (AISI 321) and 1.4550 (AISI 347), are also employed (Table 4). These steels are usually specified for towers and heat-exchanger shells, and also for many heat-exchanger tubes. The 1.4335 steel (AISI 310L) has a very low corrosion rate and is used

particularly where corrosive attack is severe, for example, if the temperature is below the dew point of nitrous gas, even at higher temperatures [59]. These conditions normally occur at the inlet to the tail-gas preheater, in the dew point region of the cooler – condenser, and at the outlet of the feedwater preheater. Corrosion at these locations is caused mainly by reevaporation of nitric acid condensate, which brings the acid concentration up to the azeotropic level (69 % HNO_3). The acid is then very aggressive, even in the vapor phase. Corrosion can take place in the boiler feedwater preheater if condensate forms at the outlet. Reheating of the condensate by the hot process gas can lead to critical conditions. Process design parameters should normally be selected so as to avoid condensation; material no. 1.4306 is then adequate. If, however, condensation or reboiling occurs and this steel cannot be used, 1.4335 should be employed [60].

In plants producing concentrated nitric acid, aluminum (99.8 %), ferrosilicon, tantalum, and special austenitic steels are used. Because tantalum is very expensive, it is employed only with boiling concentrated nitric acid. Ferrosilicon can be used only in castings because of its brittleness.

1.3.4. Processes

Figure 14 illustrates the steps necessary for implementation of the Ostwald process. Industrial processes differ in the sequence and design of these steps. This section describes processes for the production of weak acid [61, pp. 61 – 98] and strong acid [61, pp. 99 – 130].

1.3.4.1. Weak Acid Processes

The first industrial plants for the production of weak acid employed atmospheric combustion and low-pressure absorption [3]. This type of plant is no longer built. It was followed by a process employing atmospheric combustion and absorption at medium pressure. This process has the advantage of lower absorption costs because the marked improvement in absorption obtained with the pressure generated by a nitrous gas compressor allows the apparatus to be downsized. The energy of compression can be partially recovered with a tail-gas turbine. To circumvent the difficulty of operating a compressor for nitrous gas and obtain a further decrease in plant volume, to ammonia was also oxidized at medium pressure. This type of process is particularly economical for smaller capacities and is thus described first.

As plant capacities continued to grow and lower tail-gas levels of NO_x were necessary the absorption pressure was increased still further. Lower energy costs and shorter depreciation periods in the United States have led to a preference for the high-pressure process, whereas more favorable consumption and production figures in Europe have favored the dual-pressure process with medium-pressure combustion and high-pressure absorption.

The principle of medium- and high-pressure (monopressure) plants is that air for ammonia oxidation and NO_x absorption is compressed to the desired pressure. The "primary" air for oxidation is then mixed with ammonia and forced through the burner. The "secondary" air for stripping dissolved NO_x out of the raw acid and oxidizing the intermediate nitrogen monoxide is supplied upstream of the absorption tower. The tail gas is heated and then expanded in a turbine (on a common shaft with the compressor) to produce mechanical energy. The remaining drive power is supplied by a steam turbine running on process steam.

Medium-Pressure Process. Figure 27 is a flow sheet of a medium-pressure process (ca. 550 kPa). Liquid ammonia is evaporated at ca. 700 kPa in the ammonia evaporator (a). The cold generated can be used in the absorption step. Water is removed from liquid ammonia in an ammonia stripper (b). The ammonia – water blowdown mixture is evaporated batchwise with steam. Residual aqueous ammonia can be used in fertilizer production. The ammonia vapor is heated with steam to ca. 90 °C in the ammonia preheater (c) and then filtered (d). If necessary, a small stream of ammonia is diverted to tail-gas treatment.

All the air needed for the process is sucked in through the air filter (f) by the air compressor (g). The compressed air is divided into two substreams in a tail-gas preheater (h). The secondary air goes to the bleacher (x) for stripping raw acid.

Figure 27. Simplified flow sheet of a medium-pressure process
a) Ammonia evaporator; b) Ammonia stripper; c) Ammonia preheater; d) Ammonia gas filter; e) Ammonia – air mixer; f) Air filter; g) Air compressor; h) Tail-gas preheater III; i) Reactor; j) Waste-heat boiler; k) Tail-gas preheater I; l) Economizer; m) Tail-gas preheater II; n) Feedwater preheater; o) Cooler – condenser; p) Absorption tower; q) Ammonia – tail-gas mixer; r) BASF catalytic tail-gas reactor; s) Tail-gas expansion turbine; t) Feedwater tank with deaerator; u) Steam drum; v) Steam turbine; w) Steam turbine condenser; x) Bleacher

The secondary airstream exiting the bleacher is laden with NO_x and is added to the nitrous gas before it enters the absorption tower (p). The greater part of the process air, the primary air, is mixed with the superheated ammonia in the ammonia – air mixer (e); it then flows through the mixed-gas filter (not illustrated) and, now cleaned, enters the reactor (i) where ammonia reacts with oxygen in the primary air over the platinum – rhodium catalyst, yielding nitrogen monoxide and water. The reaction is exothermic and proceeds at ca. 890 °C. The nitrous gas stream is cooled in the waste-heat boiler (j), raising steam. Nitrogen monoxide is oxidized to nitrogen dioxide in the downstream piping and equipment, heating the nitrous gas stream. Further heat recovery takes place in the tail-gas preheater (k) and the economizer (l). After exiting the economizer, the nitrous gas stream is cooled in a second tail-gas preheater (m). Condensate can form in the next unit downstream, the feedwater preheater (n), which is located directly on the inlet of the cooler – condenser (o). Additional water of combustion condenses out in the cooler – condenser before the nitrous gas stream is mixed with the NO_x-laden secondary air and admitted to the absorption tower (p). The acid condensate from the feedwater preheater and the cooler – condenser flows directly into the bottom of the gas cooler – condenser. This acid condensate is then delivered by an acid condensate pump to a tray with the appropriate concentration in the absorption tower.

In the lower part of the tower, the nitrous gas is oxidized further, thus reaching the necessary degree of oxidation before entering the absorption section. The tower contains sieve trays through which the gas flows countercurrent to the acid. The product acid concentration is attained on the lowermost absorption tray of the tower. The acid is then pumped to the bleacher (x), where dissolved NO_x is stripped, before the

acid is stored in tanks. Chlorides in the absorption tower feed accumulate on trays where the acid concentration is ca. 21 wt %. Because of the danger of corrosion, these trays must be emptied into the product acid tank from time to time. Cooling water flowing through coils on the sieve trays removes heat generated by the oxidation of nitrogen monoxide to nitrogen dioxide and its further conversion to nitric acid. Part of the heat absorbed by the cooling water is utilized to evaporate ammonia. A demister in the head of the tower collects liquid droplets entrained in the tail gas; the condensate runs back to the last tray of the absorption tower.

The tail gas absorbs heat from the secondary air and the nitrous gas in three tail-gas preheaters. In the BASF catalytic tail-gas treatment (r; see also Section 1.4.2.3), ca. 60 vol % of the NO_x in the tail gas is selectively reacted with ammonia. Hot tail gas containing < 200 ppm NO_x goes to the tail-gas expansion turbine (s), in which mechanical energy is produced to drive the air compressor. Finally, the tail gas is discharged to the atmosphere via the stack.

The tail-gas expansion turbine supplies part of the power needed to drive the air compressor. The rest is generated by a condensing steam turbine supplied with product steam. The turbine may be bled. The steam turbine condensate goes to the boiler feedwater preheater (n) where it absorbs heat from the NO_x gas and then flows through the deaerator into the feedwater tank (t). Nondeaerated feedwater from the battery limitalso flows via a preheater into the feedwater tank. The boiler feedwater pump raises the pressure of the deaerated feedwater to the requisite boiler pressure. Product steam is raised with heat from ammonia combustion in the waste-heat boiler (j).

Most of the steam generated in the waste-heat boiler drives the condensing steam turbine. The remainder can be utilized in the ammonia preheater and stripper and for deaerating the feedwater; any excess is exported as product steam.

High-Pressure Process. Figure 28 shows a high-pressure process running at ca. 1 MPa. Liquid ammonia is fed into the evaporator (a), where it is evaporated at ca. 1.15 MPa against warm water. The evaporation temperature rises slightly above 35 °C as the water content builds up in the evaporator. The ammonia – water blowdown mixture is evaporated with low-pressure steam in the ammonia stripper (b). The residual ammonia concentration is ca. 2.5 %.

Ammonia exiting the evaporator system is heated to ca. 130 °C in the ammonia preheater (c), and contaminants are removed in the ammonia gas filter (d).

Air is sucked in through the air filter (f) and compressed to ca. 1 MPa in an air compressor (g) with interstage cooling (h). The primary air (ca. 80 % of the total) is heated to ca. 180 °C against nitrous gas in the air heater (m) and then fed to the ammonia – air mixer (e). The mixed gas stream has a temperature of ca. 175 °C and contains 10.7 vol % ammonia. It passes through a filter (not illustrated) into the reactor (i) where the ammonia and atmospheric oxygen react over the platinum – rhodium catalyst at ca. 900 °C to form mainly nitrogen monoxide and water.

The reaction gases next pass through the waste-heat boiler (j), where they are cooled to ca. 400 °C. The heat is used to raise high-pressure steam and superheat it to 500 °C in the preevaporator, superheater, and reevaporator of the boiler.

The boiler system is fed with condensate from the steam turbine condenser (w) plus demineralized water from the battery limit. Both streams are led to a tank and from there go through the feedwater preheater (n) to the deaerator mounted on the feedwater tank (t) and operating at a slight gauge pressure. The tank serves as suction vessel for the feedwater pumps, which deliver water through the economizer into the boiler drum (u).

The water – steam mixture in the evaporator is circulated by the boiler circulation pump. Saturated steam and water are separated in the boiler drum (u).

After leaving the waste-heat boiler (j), the nitrous gas is cooled to ca. 260 °C in a tail-gas preheater (k). After passing through a run of piping for oxidation, nitrous gas gives up more useful heat in the economizer (l), and its temperature falls to ca. 210 °C. After another oxidation run, the stream is led into the air heater (m) and cooled to ca. 180 °C. The heat recovered is used to preheat the primary air.

Before the nitrous gas is led into the gas cooler – condenser (o), it passes through feedwater preheaters and through the warm-water heater (n) both mounted on the two inlets of the cooler – condenser. The nitrous gas is cooled to

Figure 28. Simplified flow sheet of a high-pressure process

ca. 115 °C and partly condensed before entering the cooler – condenser.

In the water-cooled cooler – condenser (o), the gas is cooled to < 50 °C so that water formed during ammonia oxidation condenses to produce ca. 45 % acid. This product is delivered to the appropriate tray of the absorption tower (p) by the acid condensate pump. The NO_x-laden secondary air recycled from the bleacher (x) is mixed with the nitrous gas stream before it is fed into the tower (p).

In the sieve-tray absorption tower (p) the nitrous gas flows countercurrently to the process water fed at the column head, and nitric acid is formed. Heat from the absorption tower is transferred to the cooling water. Raw acid from the absorption tower is treated with secondary air in the bleacher (x), then delivered to battery limit with the aid of the system pressure.

Tail gas exits the absorption tower at ca. 20 – 30 °C. It is heated to ca. 80 °C in a tail-gas preheater (q) against the tail-gas stream from the expansion turbine. The tail gas is further heated to 140 °C against low-pressure steam (r) and then to ca. 375 °C in a tail-gas preheater (k). It is subsequently expanded in the tail-gas turbine (s); this step produces ca. 70 % of the energy required to drive the air compressor.

Tail gas exits the turbine at ca. 135 °C and is led to a tail-gas preheater (q), where it is cooled to ca. 90 °C before being discharged through the stack.

The rest of the power needed to drive the air compressor can be supplied by a pass-out condensing steam turbine (v). The superheated steam is delivered to the steam turbine or exported. Part of the steam supplied to the turbine is withdrawn as low-pressure steam before admission to the condensing section. This low-pres-

sure steam is used in the plant or exported. The rest of the steam supplied to the turbine passes through the condensing section and is condensed in the steam turbine condenser (w).

Dual-Pressure Process. The dual-pressure process combines the favorable economics of medium-pressure combustion with the efficiency of high-pressure absorption. Figure 29 is a flow sheet of such a plant with ammonia combustion at 0.5 MPa and absorption at 1.1 MPa.

Liquid ammonia is fed to the ammonia evaporator (a), which is under a pressure of ca. 0.65 MPa. The entire stream then goes to ammonia evaporator I, where ca. 80 % of the ammonia is evaporated against cold water at a constant temperature of ca. 12 °C. Residual liquid ammonia is fed to ammonia evaporator II (not illustrated) and evaporated at varying temperatures against cooling water. The evaporation temperature increases from 12 °C to ca. 20 °C as water content builds up in the evaporator. Ammonia evaporator II is designed so that the entire ammonia stream can be evaporated in it, if necessary, at a maximum temperature of 20 °C. If the water content or the evaporation temperature in ammonia evaporator II is too high, the ammonia – water mixture is blown down and fed to the ammonia stripper (b). Ammonia is stripped to a residual content of ca. 2.0 % as the temperature is raised to 150 °C with low-pressure steam. The residue, greatly depleted in ammonia, is discharged.

Gaseous ammonia from the evaporator system is passed through the ammonia gas filter (c) to remove contaminants, then heated to ca. 150 °C in the ammonia preheater (d).

Air is sucked through the filter (f) and compressed to 0.5 MPa in the compressor (g). About 86 % of the air is fed as primary air to the ammonia – air mixer (e). The mixed gas stream has a temperature of ca. 220 °C and contains ca.

10 vol % ammonia. It is transported through the gas-mixture filter (not illustrated) to the reactor (h). Here, ammonia reacts on the platinum–rhodium catalyst with atmospheric oxygen at 890 °C to produce a 96.5 % yield of nitrogen monoxide and water.

The reaction gases next pass through the waste-heat boiler (i) and are cooled to 355 °C. The heat is used to raise high-pressure steam in the preevaporator, superheater, and reevaporator of the boiler.

The boiler system is fed with condensate from the steam turbine condenser (x) plus demineralized water from the battery limit. Both streams are led to a tank and then pass through the feedwater preheater (m) to the deaerator mounted on the feedwater tank (u). The tank serves as a suction vessel for the feedwater pumps, which deliver the water through the economizer (k) into the steam drum (v).

The water–steam mixture in the evaporator is circulated by the boiler circulation pump. Saturated steam and water are separated in the steam drum (v).

After exiting the waste-heat boiler and passing through a run of piping for oxidation, the nitrous gas is cooled from 390 to 280 °C in tail-gas preheater III (j). After further oxidation, it enters the economizer (k), where it is cooled from 310 to 200 °C. The nitrous gas gives up further useful heat to the tail gas in tail-gas preheater II (l) and its temperature falls to ca. 170 °C.

The gas passes through the feedwater preheater (m), mounted on the cooler–condenser inlet and thereby cools to ca. 100 °C. In the water- cooled cooler–condenser I (n), the gas is cooled to < 50 °C so that the water formed during ammonia oxidation condenses. A ca. 43 % acid results and is pumped to the appropriate tray of the absorption tower (s). The secondary air laden with NO_x and recycled from the bleacher (y) is now mixed with the nitrous gas stream. The mixed stream is then led into cooler–condenser II (o), where it is cooled to ca. 45 °C against chilled water. More water condenses and a ca. 52 % acid is formed, which is forwarded for absorption along with acid formed in cooler–condenser I. The gas is passed through a mist collector (not illustrated) upstream of the nitrous gas compressor (p).

The nitrous gas is compressed to 1.1 MPa in the compressor (p) and has an outlet temperature of ca. 130 °C. It passes to tail-gas preheater I (q), where it is cooled to ca. 75 °C. Downstream of the preheater is cooler–condenser III (r), which the nitrous gas leaves at 50 °C. The resulting acid condensate has a concentration of ca. 58 wt % and is mixed with the raw acid from the absorption column.

From cooler–condenser III the nitrous gas, now at least 90 % oxidized, enters the absorption tower (s). The gas first passes through oxidation trays that receive only a slight flow of liquid, to attain the degree of oxidation needed for equilibrium with 68 % acid. In the absorption section, gas and liquid move countercurrently. Required process water is pumped to the tower head. The 68 % raw acid is withdrawn from the first absorption tray and then treated with secondary air in the bleacher (y). It is delivered to the battery limit with the aid of the system pressure.

Approximately 80 % of the heat generated by absorption is transferred to the cooling water and the remainder to the chilled water employed in the last part of the absorption step where very little heat of reaction is liberated.

The tail gas contains $< 150-200$ ppm NO_x and exits the absorber at 20 °C. It is heated to 110, 200, and finally 350 °C in the three downstream tail-gas preheaters (q, l, and j) before being expanded in the tail-gas turbine (t). The turbine supplies ca. 67 % of the power required by the air and the nitrous gas compressors. The expanded tail gas has a temperature of ca. 100 °C and is discharged through a stack.

The remaining power required to drive the rotating machinery can be obtained from a pass-out condensing steam turbine (w). Superheated steam is fed to the turbine or exported. Part of the steam supplied to the turbine may be withdrawn as low-pressure steam before it enters the condensing section. This low-pressure steam may be used in the plant or exported. The remainder of the steam fed to the turbine passes through the condensing section and is condensed in the steam turbine condenser (x).

Comparison of Medium- and High-Pressure Processes [62]. Two trends can be seen in the worldwide development of weak acid processes. First, from the process-engineering standpoint, a progression occurs from low- through medium- to high-pressure processes [5]. Second, capacities continue to increase; single-

Table 5. Comparison of significant specific consumption figures for nitric acid plants (values are given per tonne of 100 % HNO_3, the tail gas contains < 200 ppm of NO_x)

Parameter	Monopressure processes		Dual-pressure process
	Medium pressure	High pressure	
Operating pressure, MPa	0.55	1.080	0.45/1.1
Ammonia, kg	282 ∗	283	279

Low-pressure heating steam, t	0.1	0.1	0.1
High-pressure excess steam, t (2.5 MPa, 400 °C)	0.87	0.78	0.81

∗ Includes 1 kg NH_3 for NO_x reduction from 600 to < 200 ppm. ∗∗Includes water for steam turbine compressor.

train plants producing up to 2000 t of nitric acid per day are now being built. In Europe, the dual-pressure design is preferred for larger plants, whereas smaller ones employ the monopressure design. Where feedstock and energy prices are low, monopressure operation offers special advantages; low investment costs ensure a quick payout, particularly in North America. If, on the other hand, feedstock and energy prices are very high (as in Europe), yield and energy efficiency must be maximized, so higher investment costs are acceptable. Table 5 compares consumption figures per unit product for monopressure and dual-pressure processes.

New pollution control regulations and the energy crisis of the mid-1970s have also led to the development of new processes or the improvement of existing ones. To avoid the need for catalytic tail-gas treatment in large-tonnage plants (and thus an increase in specific ammonia consumption), new facilities employ higher absorption pressures.

1.3.4.2. Concentrated Acid Processes

Industrially produced nitric acid contains 50 – 70 wt % HNO_3. This is high enough for fertilizer production, but nitration processes in industrial organic chemistry call for concentrated acid (98 – 100 %). Distillation, the simplest way to concentrate dilute acid, fails because nitric acid and water form an azeotrope (68.4 % HNO_3 at atmospheric pressure).

Concentrated nitric acid is manufactured directly or indirectly [63]. In the *direct process*, the water generated in ammonia combustion is withdrawn by rapid cooling to give a nitrous gas mixture from which concentrated acid can be produced directly in one of two ways. First, the completely oxidized NO_x can be separated in liquid form by absorption in concentrated nitric acid and then led to a reactor where it is reacted with oxygen and water (or weak acid) under pressure to yield concentrated acid. Second, nitrous gases can be reacted with azeotropic acid to form a concentrated acid that can be converted easily to concentrated and azeotropic acid by distillation. The latter product is either completely recycled or used in the production of ordinary weak acid.

In the *indirect processes*, concentration is based on extractive distillation and rectification with sulfuric acid or magnesium nitrate.

Direct Process. The essential feature of the classical direct process (Fig. 30) is that liquid dinitrogen tetroxide is produced and reacted under pressure with pure oxygen and a certain quantity of dilute nitric acid. A detailed account of concentrated acid production via azeotropic nitric acid is given in [61, pp. 99 – 130].

Ammonia Oxidation. As in weak acid processes, feed ammonia is evaporated, superheated, and filtered (see Section 1.3.4.1). Evaporation takes place with the aid of water heated with process heat. Because traces of water and oil accumulate in the ammonia evaporator the sump must be drained into the steam-heated stripper from time to time. Air for ammonia combustion is sucked through a filter (a) and mixed with purified ammonia in the mixer (b). The ammonia content of the mixture is held in the range 11.5 – 12.3 vol %, depending on the temperature. The optimal combustion temperature is 830 – 850 °C. Ammonia oxidation takes place over conventional platinum – rhodium cat-

alysts in the reactor (d). The heat of reaction is used to raise steam in a waste-heat boiler and an economizer. The process gas exits the economizer at ca. 170 °C and is then cooled to 25 °C in a cooler – condenser (e), giving an acid containing ca. 2 – 3 wt % nitric acid. The cooler – condenser is specially designed to condense as much water as possible without much NO_x absorption. Part of the process heat is also transferred to the warm water used for ammonia evaporation. The weak condensate generated in the cooler – condenser is used as scrub liquor for final absorption.

Oxidation of Nitrogen Monoxide. Secondary air is mixed with the cooled process gas to oxidize nitrogen monoxide to nitrogen dioxide. The amount of secondary air must be sufficient to ensure that the tail gas has a minimal oxygen content (2.5 – 3.5 vol %) before it is discharged to the atmosphere. The concentrated nitric acid venting system is connected to the secondary air intake in such a way that oxygen and nitrogen oxides liberated on venting are recycled to the process. The nitrogen monoxide gas and secondary air are compressed together to ca. 0.14 MPa (f). After further cooling (g) to remove the heat of compression, the mixture enters the oxidation tower (h), which is usually equipped with sieve trays. Tube coils on the trays remove the heat of oxidation. To maintain a liquid level on all trays, acid from the tower bottom is pumped (recirculated) to the head.

Final Oxidation of Nitrogen Monoxide. The nitrous gases leaving the oxidation tower are approximately 95 % oxidized and are led to a final oxidizer (postoxidizer) (j) where they are completely oxidized by desorption of concentrated nitric acid. The acid moves countercurrently to the nitrous gases. Water produced in this reaction dilutes the concentrated acid; acid leaving the postoxidizer contains ca. 75 % HNO_3. Flow control of the concentrated nitric acid feed into the postoxidizer is important because too high a rate lowers the output of concentrated acid, whereas too low a rate displaces final oxidation into the absorber, with the result that the concentrated nitric acid entering the absorption tower is too dilute. The product gas is saturated with nitric acid vapor. For the next step, absorption, the process gas is cooled to −10 °C against brine in a cooler (l). Virtually all the nitrogen dioxide is dimerized to dinitrogen tetroxide at this temperature.

Absorption of Dinitrogen Tetroxide. The nitrous gases are completely dimerized to dinitrogen tetroxide and, in this condition, are fed into the absorber (m). The absorber consists of four sections, each packed with ceramic Raschig rings. The dinitrogen tetroxide is absorbed in concentrated nitric acid that comes from the bleacher and is cooled to ca. −10 °C (k, u). The

acid leaving the absorption tower contains ca. 25 – 30 wt % dinitrogen tetroxide and is pumped to the raw acid tank (o).

Final Absorption. The gas exiting the absorption tower is practically free of nitrogen dioxide but saturated with nitric acid vapor. The vapor is removed by scrubbing in the final absorber (n), which consists of two sections. The scrub liquor (weak nitric acid from the cooler – condenser) is recirculated or used to make up the water balance in the stirred tank.

Dinitrogen Tetroxide Production. The laden concentrated nitric acid is sent from the raw acid tank (o) to the bleacher (t), which consists of a stripping section and a reboiler. The acid enters the head of the tower and flows downward countercurrently to the nitric acid vapor, which strips nitrogen dioxide from the concentrated nitric acid. The bleached concentrated acid goes to the reboiler section of the bleacher, where it is partially evaporated and partially withdrawn as product acid. The vapor exiting the bleacher contains ca. 95 % nitrogen dioxide and 5 % nitric acid. Most of the vapor condenses in a downstream precondenser (q). Dinitrogen tetroxide is liquefied in the liquefier and fed to a stirred tank (r).

Production of Concentrated Nitric Acid. The formation of concentrated nitric acid in the reactor (s) is described by the following equation:

$$4\,NO_2(\rightleftharpoons 2\,N_2O_4) + O_2 + 2\,H_2O \rightleftharpoons 4\,HNO_3$$

This requires a $N_2O_4 - H_2O$ molar ratio of 1 : 1 and a weight ratio of 5.11 : 1. The reaction time can be considerably shortened if dinitrogen tetroxide is present in excess. On the other hand, an excess of dinitrogen tetroxide lowers the production rate of the reactor and increases the dinitrogen tetroxide recycle rate, resulting in higher steam consumption for bleaching and a greater cold requirement for dinitrogen tetroxide liquefaction.

The $N_2O_4 - H_2O$ ratio, denoted the R factor, is the most important criterion for monitoring reactor operation. In practice, it fluctuates between 6.5 and 7. A product concentration of > 98 wt % nitric acid requires a higher R factor. The economically most favorable R factor can be found only by empirical means; the ratio can be varied to achieve optimal operating conditions. The makeup acid used to maintain the water balance of the raw acid mixture is taken from the bottom of the final absorber (n).

Concentrated nitric acid is formed in the reactor (s) at ca. 5.0 MPa and 60 – 80 °C. High mechanical strength and corrosion resistance are needed, but these two requirements cannot be satisfied by any one material. The reactor thus has a carbon steel jacket to provide mechanical strength and a pure aluminum inner shell to provide corrosion resistance. Unreacted oxygen is supplied to the suction of the nitrous gas blower via the venting system. The concentrated nitric acid product is led to the raw acid tank (o) and then to the bleacher. The bleached concentrated acid is cooled to + 30 °C (u). Most of the concentrated nitric acid is returned to the absorption tower and final oxidation.

Indirect Processes. Two types of indirect process are used to produce concentrated nitric acid (i.e., product containing > 97 wt % HNO_3):

1) Sulfuric acid process
2) Magnesium nitrate process

Both concentration techniques are based on extractive distillatfication. Weak acid is first produced by a conventional process (Section 1.3.4.1), then a third component is added to extract the water so that up to ca. 99 % nitric acid can be distilled from the ternary mixture.

Figure 31. Simplified flow sheet of a process for preconcentration of nitric acid
a) Preconcentrating tower; b) Separator; c) Recirculating evaporator system; d) Cooler

The starting product is ordinary commercial nitric acid (ca. 55 – 65 % HNO_3). Weaker acids

can be preconcentrated in a single-stage or multistage process to give ca. 68 wt % nitric acid. Figure 31 illustrates a single-stage apparatus. Preconcentration takes place in a continuous countercurrent distillation tower (a), which can be of either the packed or the bubble-tray type. The system includes one or, if appropriate, two preheaters, a recirculating evaporator system for the tower bottom, a stripping and rectifying section for the tower, an overhead condenser, and a reflux separator (b).

Sulfuric Acid Process. Sulfuric acid can be used as extracting agent (see also → 4. Distillation and Rectification). The concentrated nitric acid product is clear and colorless; it contains 98 – 99 wt % nitric acid and < 0.05 % nitrogen dioxide.

Consumption figures for the production of 1 t of 99 % nitric acid from dilute nitric acid are given in Table 6.

Table 6. Consumption figures for the production of 1 t of 99 % HNO_3 from dilute nitric acid by the sulfuric acid process∗

The nitric acid concentration step now operates with indirect heating, an advance over earlier technologies that reduces steam consumption by as much as 50 %.

The materials of construction are highly corrosion resistant. Towers are made of borosilicate glass, enameled steel, and steel – polytetrafluoroethylene. Heat exchangers are made of glass, polytetrafluoroethylene, stainless steel, tantalum, titanium, high-purity aluminum, and special alloys.

Figure 32 is a flow sheet of a plant making concentrated nitric acid by the sulfuric acid process. The feed nitric acid, concentrated to about 68 wt %, is preheated (e) and then fed into the distillation tower (a). At least 80 wt % sulfuric acid is fed to the head of the tower. The part of the tower above the nitric acid inlet, which is irrigated with sulfuric acid, can be regarded as the rectifying section, with the sulfuric acid also functioning as reflux. The part of the tower below the nitric acid inlet is the stripping section.

A circulating evaporator system takes care of bottom heating. The ca. 70 % sulfuric acid leaving the bottom of the tower goes to the concentrator (c), which operates under vacuum (8 kPa). The overhead vapor product from the tower is condensed to form 99 % nitric acid and then deaerated (b). The tail gases, which still contain nitric acid vapor, are scrubbed with dilute nitric acid (d).

Magnesium Nitrate Process. In this process a magnesium nitrate solution is used to extract water from the nitric acid. The resulting dilute magnesium nitrate solution is restored to the de-

Figure 33 is the flow sheet of a plant making concentrated nitric acid by the magnesium nitrate process. Weak acid is fed to the dewatering tower (a). Extractive distillation with a concentrated (72 wt %) solution of magnesium nitrate at 140 °C gives an overhead product containing 99 % nitric acid. A small fraction of the condensed overhead product is refluxed to the dewatering tower. The bottom of the tower is heated, and the dilute magnesium nitrate solution, containing < 0.1 % nitric acid, is led to the vacuum evaporator (b). Condensed weak acid is processed in the recovery tower (c) and recycled if appropriate. The tail gas still contains nitric acid vapor and can be scrubbed with dilute nitric acid (c).

Comparison of Indirect Processes. Which concentration process is better suited to a given task must be decided case by case. From a process-engineering standpoint, the magnesium nitrate process has the following advantages:

1) The installation is very compact. No holding tanks are needed, which reduces energy losses.
2) Because the reconcentration step for magnesium nitrate is carried out in stainless steel vessels, virtually no critical construction materials are required.
3) Magnesium nitrate can be transported in sacks, and is therefore much easier to handle than sulfuric acid.
4) The weak nitric acid condensate, which is produced when the magnesium nitrate solution is reconcentrated, is partly reused in NO_x absorption. Losses of nitric acid are very slight.

As in weak acid production, development of concentrated acid production has followed different paths in the United States and the Federal Republic of Germany (and, in part, in Europe). In the United States estimated operating costs are significantly lower for concentration with magnesium nitrate than with sulfuric acid. The U.S. view is largely that, even after the change from autoclaves to continuous direct production, the equipment cost (i.e., investment cost) is too high for the latter process to be competitive.

1.4. Environmental Protection

In recent years, more stringent water pollution regulations have taken effect and legislative provisions for air pollution have been amended. New processes have been developed and introduced to significantly reduce pollutant emissions from nitric acid plants. The problem of nitrogen oxide pollution is treated in more detail in → Air.

1.4.1. Wastewater

Wastewater problems can be overcome by appropriate design of the nitric acid plant. An especially simple form of wastewater treatment can be employed when the nitric acid is processed directly for the production of mineral fertilizers.

The solution from ammonia stripping contains up to 10 % ammonia; it can be neutralized with nitric acid and then subjected to absorption along with process water. The acid product then contains a small amount of ammonium nitrate, but this is not a problem when the acid is processed into mineral fertilizers.

Leaks from pumps, vessels, etc., are pumped into a separate acid drain tank, and then processed directly or indirectly. The apparatus used for this purpose is completely separate from the sewage system and thus prevents contamination of wastewater.

If heat is removed by recooling systems, cooling water blowdown is fed into the wastewater system to limit thickening of the cooling water. Fresh water must be supplied to compensate for the blowdown and evaporation losses. Corrosion inhibitors, hardness stabilizers, and in some cases, biocides are also carried out of the system by blowdown.

1.4.2. Stack Gas

Obsolescent nitric acid plants can be recognized by their strongly colored yellow to reddish brown plumes of stack gas. The coloration is due to nitrogen dioxide. Some stack gases contain up to 3000 ppm NO_x; very old plants may surpass these values [64].

The absorption of nitrous gases with water forms part of the nitric acid process. However, the laws of nature prevent complete absorption, and some residual emission cannot be avoided (see Section 1.3.2). These emissions can be minimized by optimizing process conditions, increasing the efficiency of absorption, or using special tail-gas treatment methods.

Crucial parameters for the absorption of nitrous gases in water are the following [65]:

1) Pressure
2) Temperature
3) Reaction volume
4) The efficiency of the absorption tower
5) The partial pressures of nitrogen oxides and oxygen

Emissions in the Federal Republic of Germany in 1986 totaled ca. 3×10^6 t NO_x [66]. Transportation, households, and small consumers accounted for ca. 66 % of this; power plants and district heating plants for ca. 25 %; and industry, including furnaces, for ca. 9 %. Nitrogen oxides from nitric acid production were responsible for < 1 % of the total emissions.

1.4.2.1. Emission Limits

Heightened sensitivity to environmental concerns, coupled with the need for larger and more efficient production systems, will lead to further reductions in NO_x emissions. Legislators are following this trend and modifying pollution limits in accordance with changing technical capabilities.

At the beginning of the 1980s the first general administrative regulation was issued in the Federal Republic of Germany under the Federal Pollution Control Act: the Technische Anleitung zur Reinhaltung der Luft (TA-Luft; Technical Instructions for Air Pollution Control) [67]. This regulation and the corresponding VDI guidelines [68] form the basis for issuing operating permits. Regulations in many other countries are based on these guidelines.

The designation NO_x is commonly used to specify emission and concentration values because stack gases always include mixtures of nitrogen oxides. For the purpose of standardization, the oxides are calculated in terms of nitrogen dioxide. The acceptable concentrations from TA-Luft 1986 [67] are

1) Mass of substances emitted as mass concentration in units of g/m^3 or mg/m^3, referred to the volume of stack gas at standard conditions (0 °C, 101.3 kPa) after deducting the moisture content of water vapor, or to the volume of stack gas at standard conditions (0 °C, 101.3 kPA) before deducting the moisture content of water vapor; and
2) Mass of substances emitted, referred to time, as mass velocity in units of kg/h, g/h, or mg/h; and
3) Ratio of the mass of substances emitted to the mass of products generated or processed (emission factors), as mass ratio in units of kg/t or g/t.

The usual concentration unit ppm (mL/m^3) can be converted to the prescribed mass concentration (mg/m^3) with the following factor [69]: 1 ppm = 1.88 mg/m^3 (based on monomeric NO_2 at 101.3 kPa and 298 K and ideal-gas behavior).

The TA-Luft [67] states that the emission of nitrogen monoxide and nitrogen dioxide in the stack gas of nitric acid plants must not exceed 0.45 g/m^3 as nitrogen dioxide. Furthermore, stack gases may be discharged only if colorless; as a rule, this is the case if the mass concentration of nitrogen dioxide in the stack gas does not exceed the value given by the following formula:

$$\text{Mass concentration of nitrogen dioxide}\left(\text{mg/m}^3\right) = \frac{1200}{\text{Internal diameter of stack orifice (dm)}}$$

The requirement of a colorless discharge sets a practical limit of < 200 ppm NO_x. Older low- and medium-pressure plants should comply with these standards by March 1, 1996.

Plants whose emission of nitrogen monoxide and nitrogen dioxide (as nitrogen dioxide) exceeds a rate of 30 kg/h must be equipped with devices that continuously measure the mass concentration of nitrogen oxides. Quantitative relationships between emission and ground-level concentration are also described, thus setting guidelines for stack design.

If ground-level concentration limits are exceeded, the TA-Luft emission limits are further reduced by the relevant authorities. The ground-level concentration limits for gaseous pollutants in air are as follows [67]: nitrogen dioxide, long-term exposure (IW1), 0.08 mg/m^3; short-term exposure (IW2), 0.2 mg/m^3.

1.4.2.2. Analysis

The guidelines for the measurement and monitoring of NO_x emissions from nitric acid production are specified in [67, 70, 71]. *Photometry* without auxiliary chemical reaction and *chemiluminescence* [71, c – e] are suitable for the continuous measurement of NO_x emissions [65].

Difficulties in gas sample preparation due to condensation are discussed in [71, c – g]. Additonal apparatus-related problems occur when chemiluminescence is used to measure emission of moist stack gases at higher NO_x levels. A chemiluminescence analyzer with a maximum range of 0 – 10 000 ppm has been developed [72].

For stack gases containing traces of ammonia, precipitation of ammonium salts in the measuring cells has prevented continuous measurements. Two methods useful for the discontinuous measurement of nitrogen oxide emissions [65] are acidimetric titration and the photometric phenoldisulfonic acid technique [71, a, b].

1.4.2.3. Control of NO_x Emissions

Four basic approaches are used to reduce tail-gas NO_x levels: improved absorption, chemical scrubbing, adsorption, and catalytic tail-gas reduction. Recent decades have seen intense research and development effort invested in these methods. More stringent environmental restrictions have lent special urgency to development in this area. The most important techniques are covered in this section.

Improved Absorption. Absorption efficiency depends chiefly on the absorption pressure, the number of stages, and the temperature. The temperature of the gas between stages is especially important because it governs the progress of oxidation, which is the limiting quantity for the entire absorption process (see Section 1.3.2). In an already existing nitric acid plant, the options are to expand the absorption volume and/or lower the absorption temperature. In the first approach, large additional volumes

only result in small reductions of tail-gas NO_x levels because the oxidation of nitrogen monoxide to nitrogen dioxide proceeds very slowly when the NO_x concentration is low. The drawback to this method is that added absorption volume in stainless steel is very expensive. The advantage is that it does not require any new technology. The absorption volume is added in the form of a second tower; new absorption tower designs with very few stages have been devised [73].

The use of cold energy in the absorption process greatly accelerates oxidation of nitrogen monoxide to nitrogen dioxide. The disadvantage of this method is that the necessary refrigeration equipment and piping demand further investment. Another technique involving the use of cold to lower the NO_x level is to cool the nitrous gas so that more dinitrogen tetroxide than nitrogen dioxide is formed. The dinitrogen tetroxide is then scrubbed with nitric acid at ca. 0 °C; it can be stripped out, and converted to nitric acid by the reaction

$$N_2O_4 + 1/2\ O_2 + H_2O \longrightarrow 2\ HNO_3$$

in an absorption reactor at ca. 60 – 80 °C. The technique is similar to that in concentrated nitric acid production. The method is, however, more suitable for investment in a plant being designed than for the expansion or upgrading of an existing plant.

Chemical Scrubbing. A number of patents and scientific publications deal with options for scrubbing NO_x out of tail gas. Problems related to the scrub liquor (cost, regeneration, quantity, and environmental impact) are encountered in all methods. These problems are always easier to manage if the nitric acid plant is part of an integrated chemical plant, which is usually the case. However, in some instances a nitric acid plant or sections of a fertilizer complex must operate independently. The following scrub liquors have been proposed: aqueous suspension of magnesium carbonate and magnesium hydroxide [74]; solution of vanadium in nitric acid [75]; ammonium sulfide and bisulfide [76]; milk of lime [77]; ammonia [78]; hydrogen peroxide [79]; and urea [80].

Ammonia scrubbing is used in the United States. Goodpasture (Texas) has developed a safe process based on scrubbing the tail gas with ammonium nitrate solution; nitrite formation is suppressed by aeration and the presence of free acid. The tail gas is then led through an ammoniacal scrub liquor, pH 7.5 – 8.5. The scrubbing product is a 30 – 50 % ammonium nitrate solution. The tail gas has a residual level of ca. 200 ppm NO_x.

Hydrogen peroxide scrubbing is based on the following overall reactions:

$$NO + NO_2 + 2\,H_2O_2 \longrightarrow 2\ HNO_3 + H_2O$$

$$2\,NO_2 + H_2O_2 \longrightarrow 2\ HNO_3$$

The reactions are carried on sieve trays or in packed towers with recirculation of the hydrogen peroxide solution. The advantage of this scrubbing process is that the reaction time is very fast; the disadvantage, that the hydrogen peroxide scrub liquor is expensive.

A solution containing 20 % urea and 10 % free nitric acid has also been suggested for scrubbing tail gas to remove NO_x. The process is carried at ca. 50 °C. Both nitrogen oxides are selectively reduced to nitrogen by urea, which decomposes to yield nitrogen and carbon dioxide. The process, developed by Norsk Hydro in Norway, has the advantage that urea is readily available and relatively cheap. The resulting stack gas plume is colorless but heavily laden with water vapor.

Adsorption Processes. The adsorption of NO_x by molecular sieves has long been known but has not yet been tested intensively in full-scale nitric acid plants.

The Pura-Siv-N process (Union Carbide) is claimed to reduce stack gas levels below 50 ppm nitrogen dioxide [81], but high investment costs and other problems have prevented its adoption. A patent granted to Kernforschungsanlage Jülich GmbH has a similar object [82], but again industrial experience is slight. A "wet" adsorption system has also been developed by Cofaz (France). A carbon- containing adsorbent is sprayed with water or dilute nitric acid and brought in contact with the tail gas. This process has been installed in three monopressure plants [83].

Catalytic Reduction. Catalytic reduction was the first method used to reduce NO_x emis-

sions; as early as 1924, a patent for such a process was issued to FAUSER [84]. A fuel is added, at a level below the flash point, to the nitrogen oxides which then react on the catalyst surface to form nitrogen and water vapor. Most fuels (e.g., hydrocarbons and hydrogen), however, react preferentially with the free oxygen that is always present in tail gases from nitric acid production. As a result, the nitrogen oxides are not destroyed until free oxygen has been consumed. Under these conditions the reactions with methane can be described as

$$CH_4 + 2\,O_2 \longrightarrow CO_2 + 2\,H_2O$$

$$CH_4 + 4\,NO \longrightarrow CO_2 + 2\,H_2O + 2\,N_2$$

$$CH_4 + 2\,NO_2 \longrightarrow CO_2 + 2\,H_2O + N_2$$

Ammonia can also be used as a reducing agent, preferentially reducing the nitrogen oxides:

$$6\,NO + 4\,NH_3 \longrightarrow 5\,N_2 + 6\,H_2O$$

$$6\,NO_2 + 8\,NH_3 \longrightarrow 7\,N_2 + 12\,H_2O$$

$$NO + NO_2 + 2\,NH_3 \longrightarrow 2\,N_2 + 3\,H_2O$$

$$4\,NO + O_2 + 4\,NH_3 \longrightarrow 4\,N_2 + 6\,H_2O$$

Catalytic reduction processes are accordingly classified as nonselective or selective.

Catalysts for *nonselective reduction processes* are usually based on platinum, vanadium pentoxide, iron oxide, or titanium. The fuel requirement is the stoichiometric amount needed to reduce all the oxygen present (free and in nitrogen oxides) plus a small excess (ca. 0.5 vol % CH_4).

Unfortunately, the principal byproducts of this process are carbon monoxide (≤ 1000 ppm) and hydrogen cyanide. When hydrocarbon fuels are used, the tail gas must be preheated before the reaction on the catalyst proceeds at all. The preheat temperature depends directly on the fuel selected:

Natural gas	450 – 480 °C
Propane	340 °C
Butane	340 °C
Naphtha	340 °C
Hydrogen	250 °C

The use of hydrogen allows the preheat temperature to be lowered to 150 – 200 °C but is generally too expensive.

If the quantity of fuel is not enough to reduce all the oxygen, nitrogen dioxide is reduced only to nitrogen monoxide. The stack gas is then decolorized; in some countries, this is sufficient. Complete NO_x removal generally requires preheating, multiple fixed-bed catalysts (with cooling between beds to prevent overheating), and careful heat recovery to offset part of the fuel cost.

Most nitric acid plants constructed or modified by Weatherly use nonselective catalytic NO_x abatement units with tail-gas exit temperatures of 650 – 675 °C. Some plants have gas exit temperatures > 815 °C, which is higher than the maximum for admission to the tail-gas expansion turbines. The tail gas must then be cooled, either against tail gas entering the catalytic unit or with the aid of waste-heat boilers.

In the process marketed by Du Pont the tail gas is dried, preheated, and then heated in two stages. The gas is subsequently divided into two streams. One substream is heated further, mixed with methane, and led over the first fixed-bed catalyst. The second substream is mixed with methane without further heating and led over the second fixed-bed catalyst, along with the first substream. Hot tail gases exit the bottom of the reactor and are led through the tail-gas expansion turbine, which recovers part of the work of compression.

Ammonia is the only economically relevant reducing agent for *selective catalytic processes*. The consumption of reducing agent in the selective treatment of NO_x is much smaller than in nonselective processes. Furthermore, the tail-gas temperature after reduction is significantly lower, allowing the use of simpler, cheaper construction materials. The optimal catalyst service temperature is 250 – 350 °C, but operation at up to 500 °C is possible. The costs due to the use of expensive ammonia must, however, also be considered. To prevent formation of ammonium nitrate (a potential explosion hazard) in the expansion turbine or downstream, emissions must be monitored for ammonia (10 – 20 ppm).

When BASF, Ludwigshafen [85] began work on catalytic NO_x reduction in the early 1960s, existing patents indicated the use of ammonia together with noble-metal (Pt, Rh, Ru, Pd) and iron-group (Fe, Co, Ni) catalysts [86, 87]. Alternatives were found: vanadium pentoxide, tungsten oxide, and molybdenum oxide gave excellent results. Vanadium pentoxide on an alumina support proved to be most economical.

Selective processes also require oxygen, which oxidizes part of the nitrogen monoxide to nitrogen dioxide to ensure roughly equal levels of these two oxides (the best condition for reduction). Because the BASF process operates at 200 – 350 °C, side reactions between ammonia and oxygen can be neglected. The reaction is not affected by dinitrogen monoxide, carbon dioxide, or water vapor.

For a plant with a tail-gas stream of 37 000 m^3 /h (STP) operating at a pressure of 730 kPa with an inlet NO_x concentration of 500 –1000 ppm, this process (270 °C) gives an exit concentration of 50 – 150 ppm NO_x. The treated tail gas contains < 20 ppm ammonia (usually ca. 5 ppm), and the nitrogen dioxide level is 30 –50 ppm. The stack gas is generally colorless. Careful temperature monitoring at the tail-gas expansion turbine and measurement of the ammonia level can prevent the deposition of ammonium nitrate. To minimize the pressure drop, the reactor features an annular design with inward flow (Fig. 34).

Figure 34. BASF tail-gas reactor for NO_x reduction
a) Hole plate; b) Catalyst; c) Wire gauze

Ammonia is uniformly mixed with the tail-gas stream in static mixers. The performance of the treatment process is monitored by measuring the temperature rise during reduction (ca. 10 °C/1000 ppm NO_x).

Uhde, Dortmund, as licensee, has retrofitted 14 plants with the BASF process. The tail gas, usually containing 500 – 1000 ppm NO_x, is heated to about 260 °C. Ammonia gas is added to the tail-gas stream in a mixer and then led through the reactor. The pressure drop is ca. 25 kPa. The effluent meets the requirement of colorlessness.

The HGW – Didier process, developed jointly by Hamburger Gaswerke (HGW) and Didier, Essen uses a chromium oxide catalyst with a service temperature of 265 – 350 °C. The nitric acid plant planned for DSM Miststoffen (Geleen, Netherlands) is designed for a tail-gas stream of 76 000 m^3/h (STP) with a maximum NO_x level of 2200 ppm. The exit concentration will not exceed 100 ppm NO_x. The tail gas is preheated before entering the reactor. To meet the strict emission limit of < 100 ppm, the catalyst is located in three beds. Ammonia can be admitted separately over each. The following distribution has proved most efficient: 70 % over the first bed, 20 % over the second, and 10 % over the third catalyst bed.

Other companies also have selective catalytic reduction processes for nitric acid tail gases. For example, Mitsubishi Chemical has developed a process operating at 400 – 500 °C under pressure [88, 89]. The "DN-Cat" catalyst is installed between the heat exchanger and the tail-gas expansion turbine in the conventional flow sheet.

The Weatherly selective catalytic process operates at 250 – 310 °C. The noble-metal catalysts are the same ones employed in nonselective processes, except that the fuel is replaced by ammonia.

The Bergbauforschung – Uhde process [90] is chiefly employed for stack-gas cleanup at power plants but may later find use in emission abatement at nitric acid plants. The Bergbauforschung – Uhde process for simultaneous sulfur and NO_x removal from stack gases is utilized at the cold end of the power-plant boiler, i.e., downstream of the air preheater and electrostatic filter. It employs the adsorptive and catalytic properties of "activated coke" at 50 – 150 °C. The reducing agent is again gaseous am-

monia. The technique combines a selective catalytic process for NO_x and an adsorptive one for sulfur dioxide. The catalyst is therefore installed in a moving-bed reactor.

1.5. Storage and Transportation

As a rule, nitric acid is stored in stainless steel tanks and transported in stainless steel containers.

The regulations for transport by rail [91,92] and road [93,94] differentiate among > 70 % nitric acid, 55 – 70 % nitric acid, and < 55 % nitric acid, and also between mixtures with sulfuric acid ("mixed acid") containing > 30 % nitric acid and those containing < 30 % nitric acid. Similar regulations [95] apply to transport by ship. Important transport regulations for > 70 % nitric are as follows:

IMDG Code	Class 8, D 8261, E – F 8186
UN No.	2032
RID/ADR	Class 8, no. 2 a
CFR	49: 172.101, Cor. M

Regulations for < 70 % nitric acid are

IMDG Code	Class 8, D 8260, E – F 8185
UN No.	2031
RID/ADR	Class 8, no. 2 b
CFR	49: 172.101, Cor. M

Provisions range from details of technical equipment to labeling and give instructions in case of accidents. Regulations for the road transport of nitric acid ($\leq 70\,\%$ HNO_3 emphasize the associated hazards (poisoning by inhalation of vapors, danger of chemical burns on contact with flammable substances, formation of nitrous gases). Protective equipment includes respiratory protection apparatus, goggles, and clothing affording complete coverage, as well as an eyewash bottle with pure water. In case of accident, the fire and police departments are to be notified immediately. Spilled nitric acid must not be absorbed with sawdust or other flammable material (because of the fire hazard); instead, its spread must be prevented by the construction of earth barriers.

1.6. Uses and Economic Aspects

The principal use of nitric acid is as a starting material in the manufacture of nitrogen fertilizers; large amounts are reacted with ammonia to yield ammonium nitrate (→ Ammonia Compounds, Chap. 1.2.1.). Weak acid (ca. 60 % HNO_3) is most suitable for this purpose. Smaller amounts of weak acid are used to digest crude phosphates. About 75 – 85 % of the nitric acid produced is used in the fertilizer sector. In addition, porous ammonium nitrate prills are still an important component of explosives (→ Explosives, Chap. 7.2.).

Nitric acid is used as a nitrating agent in the preparation of explosives (→ Explosives) and organic intermediates such as nitroalkanes (→ Nitro Compounds, Aliphatic) and nitroaromatics (→ Nitro Compounds, Aromatic). It is also used in the production of adipic acid (→ Adipic Acid, Chap. 4.1.).

Other applications include use as a chemical in metallurgy (e.g., as an etchant and pickling agent for stainless steels) and in rocket fuel production.

Worldwide output of nitric acid in 1987 was 26.882×10^6 t, representing a slight increase of ca. 4 % over 1976. Production in industrialized countries has stagnated or even declined, but in 1976 – 1985 increases in capacity in less industrialized countries occurred [96]. Production figures for nitric acid in 1987 follow (10^6 t):

Europe, total	16.472
United States	6.553
Eastern Europe	4.289
Asia	1.544
Federal Republic of Germany	2.112
Poland	2.136
Belgium	1.470
Spain (1986)	1.249
Italy	1.195
Hungary	1.018

2. Nitrous Acid

Nitrous acid [*7782-77-6*], HNO_2, M_r 47.01, is a moderately strong to weak acid. Its dissociation constant K in highly dilute solutions at 18 °C is 4.5×10^{-4}. The acid is stable only in cold dilute aqueous solution. It can be prepared as follows:

$$Ba(NO_2)_2 + H_2SO_4 \longrightarrow 2\,HNO_2 + BaSO_4$$

On heating in the presence of sand, glass splinters, or other sharp-edged objects, or even at low temperature, it disproportionates as

$$3\,HNO_2 \rightleftharpoons HNO_3 + 2\,NO + H_2O$$

This disproportionation reaction influences the properties of nitrous acid solutions and is important in the production of nitric acid. Nitrous acid occurs as an intermediate product when NO_x gases are absorbed in water.

By virtue of the above reaction, nitrous acid can act as both a reducing and an oxidizing agent. Strong oxidizing agents such as potassium permanganate oxidize nitrous acid to nitric acid. It can be reduced to less oxygen-rich compounds (NO_2, NO, $H_2N_2O_2$, NH_3) by alkali amalgams or by electrolytic means. Its salts (nitrites) are not stable in aqueous solution because of hydrolysis.

Nitrous acid in aqueous solutions is assumed to be in dynamic equilibrium with its anhydride:

$$2\,HNO_2 \rightleftharpoons N_2O_3 + H_2O$$

Aqueous solutions of the acid appear colorless but take on an increasingly blue coloration at 5 % dinitrogen trioxide.

Figure 35 shows the phase diagram of the $N_2O_3 - H_2O$ system with its sizable miscibility gap. Mixtures break up into a lighter layer with a high water content and a heavy layer with a high dinitrogen trioxide content.

Nitrous acid exists in two isomeric forms:

These structures lead to two series of industrially important organic derivatives:

Nitrite esters Nitrocompounds

An especially important property of nitrous acid is its ability to diazotize organic amines. With primary amines, the acid forms diazonium salts:

$$R{-}NH_2 + HNO_2 + HCl \longrightarrow [R{-}N{\equiv}N]\,Cl + 2\,H_2O$$

These salts are used widely in the manufacture of azo dyes (→ Azo Dyes).

With secondary amines, nitrosamines are formed:

$$R_2{-}NH + HNO_2 \longrightarrow R_2{-}N{-}NO + H_2O$$

Ammonia and urea react with nitrous acid to yield nitrogen:

$$NH_3 + HNO_2 \longrightarrow N_2 + 2\,H_2O$$

Figure 35. The system $N_2O_3 - H_2O$
a) Ice; b) Homogeneous liquid, water + dinitrogen trioxide; c) Liquid phase, two layers; d) Homogeneous liquid, dinitrogen trioxide + water

3. Nitrogen Oxides

Compounds of oxygen with nitrogen are considered as a class and called nitrogen oxides (often denoted as NO_x).

The known oxides and their equilibrium reactions are as follows:

Table 8. Physical properties of nitrogen oxides

Compound	N_2O	NO	NO_2/N_2O_4	N_2O_3	N_2O_5
Oxidation state

Nitrogen dioxide $\overset{+4}{NO_2} \rightleftharpoons \overset{+4}{N_2O_4}$ Dinitrogen tetroxide

$\overset{+5}{N_2O_5}$ Dinitrogen pentoxide

Nitrogen trioxide $\overset{+6}{NO_3} \rightleftharpoons \overset{+6}{N_2O_6}$ Dinitrogen hexoxide

Very little is known about nitrogen trioxide (NO_3) or its dimeric form (N_2O_6).

The compounds listed above are described in more detail in order of their oxidation state. Table 8 lists their most important physical properties.

3.1. Dinitrogen Monoxide

Properties (see Table 8). Under normal conditions (i.e., room temperature and atmospheric pressure), dinitrogen monoxide [*10024-97-2*], also called nitrous oxide, N_2O, M_r 44.01, is a colorless gas with a weak, pleasant odor and a sweetish taste. If inhaled, it can bring about a spasmodic inclination to laugh and a condition resembling drunkenness–hence, its historic name, laughing gas [97]. Two mesomeric forms in resonance with each other describe the electron distribution in the molecule [7]:

$$\overset{\delta-}{N}=\overset{\delta+}{N}=O \rightleftharpoons N\equiv\overset{\delta+}{N}-\overset{\delta-}{O}$$

Production. Dinitrogen monoxide occurs as a byproduct of denitrification (especially in the heavy use of nitrogen fertilizers) and, to some extent, in the nitrification of nitration waste acids. The compound was first prepared by PRIESTLEY, who carefully heated ammonium nitrate:

$$NH_4NO_3 \longrightarrow N_2O + 2\,H_2O$$

This is still a common route for industrial production.

In earlier processes [98], high-purity ammonium nitrate was used (contamination by organic material and chlorides had to be avoided), and temperatures up to 260 °C were reached. Today, in contrast, ammonium nitrate can be decomposed in aqueous solution containing chlorides and nitric acid at temperatures as low as 100–160 °C. This synthesis was introduced in 1970 by Hoechst [99] (Fig. 36).

The decompositon flask (a) is supplied with gaseous ammonia and nitric acid (30–100 %). Ammonia gas forms the atmosphere for the entire system, including the tower (b). A small amount of chloride ion (> 0.2 %) is maintained in the aqueous nitric acid solution in the decomposition flask (a) to accelerate the reaction. If appropriate, catalytically useful amounts of metal ions (manganese, copper, cerium, lead, bismuth, cobalt, or nickel) may also be added. Heat liberated during the reaction raises the tempera-

ture to 100 – 160 °C. The solution contains 15 – 35 % nitric acid, 30 – 50 % ammonium nitrate, 15 – 55 % water, and 0.01 – 0.1 % chloride ion. The impure product dinitrogen monoxide ascends from the decomposition flask (a) into the tower (b). Ammonia in the gas space neutralizes any entrained acidic constituents, and this reaction heats the lower part of the tower (b). The hot gas is cooled and scrubbed by an aqueous ammonium nitrate solution fed through a distributor (c). The solution collected in the bottom of the tower (b) has a temperature of 50 – 110 °C; most of itis recycled through the heat exchanger (d). The thermal energy recovered serves to heat the evaporator (e), which concentrates a small part of the solution stream for recycling to the decomposition flask (a). If the temperature profile in the system is not too low, the process does not need a heat supply.

Figure 36. Industrial production of dinitrogen monoxide [99]
a) Decomposition flask; b) Scrubbing tower; c) Ammonium nitrate distributor; d) Heat exchanger; e) Evaporator

This process has two main advantages over earlier ones: it offers a substantial energy saving and produces dinitrogen monoxide free of harmful byproducts.

The dinitrogen monoxide can easily by liquefied under pressure and is available in steel cylinders. Transport regulations for dinitrogen monoxide (compressed) are as follows:

IMDG Code	Class 2.2
UN No.	1070
RID/ADR	Class 2, no. 5 a
CFR	49: 172.102 Nonfla. G

Uses. The principal uses of dinitrogen monoxide are as follows:

1) In medicine, as an anesthetic
2) In the munitions – explosives industry, as a propellant
3) In the food industry, as a foaming agent (whipped cream)

Production data for dinitrogen monoxide are given in [100].

3.2. Nitrogen Monoxide

Nitrogen monoxide [*10102-43-9*], also called nitric oxide, NO, M_r 30.01, is a colorless, toxic, nonflammable gas at room temperature. As soon as it comes in contact with atmospheric oxygen, it is oxidized to nitrogen dioxide, a brown vapor. For physical properties, see Table 8.

Nitrogen monoxide is at dynamic equilibrium with its dimer:

$$2\,NO \rightleftharpoons N_2O_2 \Delta H = -10.5\ \text{kJ/mol}$$

At high temperature, however, the equilibrium is shifted all the way toward nitrogen monoxide. Liquid nitrogen monoxide is completely dimerized, probably as angular ONNO molecules. The nitrogen monoxide molecule contains a double bond and a three-electron bond [101]

This makes the molecule more stable than the resonant structure

so that the heat of dimerization is slight; the reaction therefore does not occur in the gas phase. The nitrogen monoxide molecule contains 11

valence electrons and thus, like all gases with an odd number of electrons, is paramagnetic.

Laboratory preparation usually involves the reaction of moderately concentrated nitric acid with copper:

$$8\,HNO_3 + 3\,Cu \rightleftharpoons 3\,Cu(NO_3)_2 + 4\,H_2O + 2\,NO$$

Nitrogen monoxide is very reactive and can, as a strongly endothermic compound, be prepared from nitrogen and oxygen in an electric flame arc:

$$N_2 + O_2 \longrightarrow 2\,NO \quad \Delta H = 90.4\,\text{kJ/mol}$$

In acidic solution (e.g., chromic acid, acidified permanganate solution, hydrochloric acid), nitrogen monoxide is oxidized to nitric acid. The combustion of nitrogen (Birkeland – Eyde, Schönherr, Pauling processes) was formerly an important method of industrial nitric acid production; however, these processes are no longer used due to the high energy cost of the arc. Nitric acid production is now based on the combustion of ammonia; nitrogen monoxide is the first reaction product and has thus gained some importance as an intermediate.

Another use of nitrogen monoxide is in nitrosation, where chlorine or bromine reacts with it to yield nitrosyl halides. In the lead- chamber process for sulfuric acid production, nitrosyl hydrogen sulfate is treated with sulfurous acid in the Glover tower, to yield nitrogen monoxide and sulfuric acid.

With aqueous iron sulfate solutions, nitrogen monoxide forms dark brown nitroso iron (II) sulfate [$(FeNO)SO_4$], thus affording a detection method for nitric acid and nitrates.

Transport regulation are as follows:

IMDG Code	Class 2, D, E – F 2095
UN No.	1660
RID/ADR	Class 2, no. 1 ct
CFR	49: 172.101 Nonfla. G

3.3. Nitrogen Dioxide and Dinitrogen Tetroxide

Nitrogen dioxide [*10102-44-0*], NO_2, M_r 46.01, is a brownish red, toxic gas with a pungent odor; for physical properties, see Table 8. It is in equilibrium with its dimer, dinitrogen tetroxide [*10544-72-6*], also called nitrogen peroxide, N_2O_4, M_r 92.01. The equilibrium is strongly temperature dependent; at higher temperature (ca. 100 °C), it is shifted almost all the way toward nitrogen dioxide.

$$2\,NO_2 \rightleftharpoons N_2O_4 \quad \Delta H = -57.2\,\text{kJ/mol}$$

Above 150 °C, nitrogen dioxide begins to dissociate:

$$2\,NO_2 \rightleftharpoons 2\,NO + O_2 \quad \Delta H = 144.1\,\text{kJ/mol}$$

This reaction goes to completion at 650 °C. Figure 37 illustrates the dissociation of dinitrogen tetroxide and nitrogen dioxide as a function of temperature.

Figure 37. Dissociation of dinitrogen tetroxide and nitrogen dioxide

The following values for the equilibrium constant of the bidirectional reaction are given in [102]:

Temperature, K	273.2	298.5	323.5	359.7
K_p (101.3 kPa)	0.017513	0.1458	0.8492	7.247

According to PAULING, the nitrogen dioxide molecule probably exists in two mesomeric forms with two ionic structures:

Dinitrogen tetroxide can be prepared in two structures, **1** exists at room temperature and is in equilibrium with **2** at low temperature:

1 **2**

Nitrogen dioxide, like nitrogen monoxide, is an odd-electron compound and therefore paramagnetic; dinitrogen tetroxide is diamagnetic. To reach an even electron number, nitrogen dioxide can give up an electron (NO_2^+, nitronium ion) or gain one (NO_2^-, nitrite anion).

Industrial production of $NO_2-N_2O_4$ employs the Ostwald process (catalytic combustion of ammonia) and constitutes the initial step in the production of nitric acid (see Section 1.3).

Other commercial processes for producing $NO_2-N_2O_4$ are the oxidation of nitrosyl chloride yielding chlorine, and the treatment of sodium nitrite with nitric acid and oxidation of the liberated nitrogen monoxide to nitrogen dioxide.

High-purity $NO_2-N_2O_4$ is obtained in the production of sodium nitrate from sodium chloride and nitric acid. The dioxide and tetroxide (oxidation state 4) are strong oxidizing agents, comparable in strength to elemental bromine. They form explosive mixtures with hydrogen; mixtures with ammonia explode even at low temperature.

Transport regulations for liquefied nitrogen dioxide are as follows:

IMDG Code	Class 2, D 2213, E – F 2099
UN No.	1067
RID/ADR	Class 2, no. 3 at
CFR A	49

Nitrogen dioxide is involved in the production of " photochemical smog" and is a major air pollutant because it is produced in all combustion processes. It is therefore subject to strict emission limits (see Section 1.4.2.1) [67].

Dinitrogen tetroxide has many applications because of its strong oxidizing action. For example, it is employed as a catalyst in oxidation reactions and as an inhibitor in the distillation of acrylates. It is also used in the manufacture of explosives, as a rocket propellant, and as a bleach.

For details on the chemistry of liquid dinitrogen tetroxide, see [103].

3.4. Dinitrogen Trioxide

Dinitrogen trioxide [*10544-73-7*], also called nitrous anhydride, N_2O_3, M_r 76.01, is stable only below 0 °C, taking the form of a deep-blue liquid. When cooled further, it solidifies as pale blue crystals. For physical properties, see Table 8.

Even below 0 °C, dinitrogen trioxide dissociates to a considerable extent:

$$N_2O_3(g) \rightleftharpoons NO + NO_2 \quad \Delta H = 40.58\,\text{kJ/mol}$$

$$2\,N_2O_3(g) \rightleftharpoons 2\,NO + N_2O_4 \quad \Delta H = 12.97\,\text{kJ/mol}$$

At 10 °C and ambient pressure, only 10 % of the molecules are in the form of undissociated dinitrogen trioxide (as $ON-NO_2$ [104]). This dissociation means that a well-defined boiling point cannot be given for dinitrogen trioxide (*bp* range −40 to + 3 °C). The compound is prepared by saturating liquid nitrogen dioxide with nitrogen monoxide:

$$NO + NO_2 \rightleftharpoons N_2O_3$$

However, because nitrogen dioxide is present mainly as the dimer, a eutectic of nitrogen monoxide and nitrogen dioxide can be postulated [105] with the empirical composition $NO_{1.56}$. The equilibrium constant for the reaction has been measured at various temperatures [106]. Because the equilibrium is easily shifted, a mixture of nitrogen monoxide and nitrogen dioxide behaves chemically like dinitrogen trioxide.

Dinitrogen trioxide occurs chiefly in nitric acid production. As much as 4 vol % of the NO_x may be present as dinitrogen trioxide. The trioxide is used in preparing high-purity alkali nitrites from alkali. It also finds use as an oxidizing agent in special fuel systems.

3.5. Dinitrogen Pentoxide

Dinitrogen pentoxide [*10102-03-1*], also called nitrogen pentoxide, N_2O_5, M_r 108.01, is the anhydride of nitric acid. It is a colorless crystalline substance that melts under pressure but sublimes

at atmospheric pressure. For physical properties, see Table 8.

In the solid state, dinitrogen pentoxide has a salt-like structure $[NO_2]^+[NO_3]^-$. It is not very stable and can undergo spontaneous explosive decomposition [107]:

$$2\,N_2O_5 \longrightarrow 4\,NO_2 + O_2$$

Dinitrogen pentoxide can be prepared by treating nitric acid with phosphorus pentoxide. It has strong oxidizing properties and reacts vigorously with organic substances. With water, the hygroscopic crystals form nitric acid:

$$N_2O_5 + H_2O \longrightarrow 2\,HNO_3 \quad \Delta H = -37.66\,\text{kJ/mol}$$

With boron trifluoride, it forms a binary compound $N_2O_5 - BF_3$ that is stable at room temperature. This compound is a good nitrifying agent. Nitrogen pentoxide has not become important in industry.

4. Toxicology and Occupational Health

Nitric Acid. Nitric acid has a caustic effect on the skin and mucous membranes. Industrial safety regulations stipulate the following workplace concentrations [108, 109]: MAK value 10 ppm (25 mg/m^3); TLV-TWA 2 ppm (5.2 mg/m^3); TLV-STEL 4 ppm (10 mg/m^3). Nitric acid reacts with and causes spontaneous ignition of organic substances such as wood shavings, saw dust, cotton, and cellulose. Spilt acid should therefore never be absorbed with such substances.

Nitric acid is classified as a hazardous substance [109, 110]. Indications of special hazards (R warnings) and safety advisories (S warnings) are given in [109].

Nitric acid > 70 %	
R 8:	Danger of fire when in contact with flammable substances
R 35:	Causes severe burns
S 23:	Do not inhale vapor
S 26:	In case of contact with eyes, flush eyes thoroughly with water and call physician
S 36:	Wear appropriate protective clothing when working
Nitric acid 20 – 70 %	
R 35:	Same as above
S 2:	Must be kept away from children
S 23, S 26:	Same as above
S 27:	Immediately remove contaminated or saturated clothing
Mixtures of nitric acid (> 30 % HNO_3) and sulfuric acid (nitrating acid)	
R 8, R 35:	Same as above
S 23, S 26, S 36:	Same as above
S 30:	Never add water to acid

Protective clothing should be worn to prevent contact with the skin. The acid must be kept away from children. In case of burns, the affected area should be washed with copious amounts of water and a doctor should be consulted. Skin burns itch and become yellow due to the formation of xanthoproteins.

Death may occur if large areas of skin are burned. Since regulation of the body temperature is disturbed, the patient must be kept warm. Protein enters the bloodstream and the patient may suffer from shock, appropriate preventive measures must therefore be taken. In case of contact with the eye, the eyelids must be opened and the eye washed with copious amounts of water. A doctor must be consulted.

Nitrous gases are released from nitric acid at room temperature, a fume cupboard should therefore be used when working with the acid. Use of respiratory protection equipment with a B, E, or NO filter is recommended.

Oral consumption of nitric acid leads to attack of the mucous membranes of the mouth, the esophagus, and the stomach. Shock may result. If concious, the patient should drink lukewarm water to dilute the acid.

Nitrous Acid. Nitrous acid is toxic because it decomposes to form nitric acid and nitrogen monoxide.

Nitrogen Monoxide. Pure nitrogen monoxide does not have any irritating effects. It reacts, however, with hemoglobin to form methemoglobin, resulting in cyanosis and possibly death. The TLV-TWA value is 25 ppm (31 mg/m^3).

Nitrogen Dioxide. Nitrogen dioxide is an irritant gas. Its MAK value is 5 ppm (9 mg/m^3), TLV-TWA 3 ppm (5.6 mg/m^3), TLV-STEL 5 ppm (9.4 mg/m^3). Inhalation of nitrogen dioxide causes pulmonary edema which may result in death (lethal dose 200 ppm). The substance is only slightly water-soluble but highly lipid-

soluble. It therefore penetrates the alveoli where it damages the capillary walls resulting in exudative inflammation. The respiratory tract is obstructed due to formation of foam. Concentrations exceeding 60 – 150 ppm produce coughing and a burning sensation in the chest. Pulmonary edema becomes apparent after 2 – 24 h. The patient suffers respiratory distress and insomnia. Chronic exposure to low doses results in coughing, headache, loss of appetite, and gastrointestinal disorders. Patients should be kept under clinical observation. Inhalation of ammonia from ammonium hydrogen carbonate is recommended.

If the presence of nitrous gas is to be expected a gas mask should be worn (NO filter).

Dinitrogen Monoxide. Dinitrogen monoxide (laughing gas) does not irritate the mucous membranes. It has a powerful analgesic action but is only weakly narcotic. The gas displaces nitrogen from air-filled body cavities (middle ear, sinuses, intestines, brain ventricles) resulting in an increase in pressure. After chronic exposure, polyneuropathy and myelopathy have been observed. TLV-TWA value is 50 ppm (90 mg/m^3).

1. Introduction

Nitrides occur rarely in nature. Titanium nitride, TiN, has been detected in silicate meteorites as the mineral osbornite [1,2]. Titanium nitride and titanium carbonitride, Ti (C, N), sometimes occur in the form of golden-yellow crystals in pig iron (blast furnace cubes). Titanium carbonitride was first described by WOLLASTON in 1822 and was identified by chemical analysis as Ti $(C_{0.2}N_{0.8})$ in 1850 by WÖHLER [3].

At the beginning of the 20th century transition-metal nitrides attracted particular interest because of their special properties such as high degree of hardness, high melting point, metallic luster, and superconductivity [4,5]. However, the first industrial application of a nitride was the use of calcium cyanamide as a fertilizer. Calcium cyanamide is produced by the reaction of nitrogen with calcium carbide; on contact with moisture in the soil it gradually releases nitrogen in the form of ammonia with the formation of several intermediates.

Classification. Nitrides can be classified according to their bonding character. Four main groups can be distinguished [6]:

1) The *ionic or saltlike nitrides* of the alkali metals, alkaline-earth metals, and of metals belonging to group 3 of the periodic table. These nitrides react with hydrogen ions to form ammonium ions.
2) The *covalent nitrides* are formed with elements of groups 13 – 15 (e.g., BN, Si_3N_4). These compounds are usually very hard; they are nonconductors or semiconductors.
3) The *transition-metal nitrides* are classified as interstitial nitrides; the bonding character is primarily metallic.
4) The *molecule-forming nitrides* of the main group elements 15 – 17 are often volatile and have low melting points. They can be explosive and decompose easily.

Synthesis. Chemical reactions most frequently used to prepare nitrides include:

1) The nitriding of metals (in powder or compact form) or metal hydrides with molecular or atomic (activated) nitrogen or in a stream of ammonia, possibly in the presence of a liquid metal (auxiliary metal technique) or at high pressure;
2) The reaction of chlorides or organometallic compounds with a nitrogen – hydrogen mixture or ammonia;
3) The reaction of metal oxides with carbon, combined with simultaneous nitriding in the presence of nitrogen or ammonia in the presence of a reducing agent such as carbon; and

10.1002/14356007.a17_341

4) The reaction of metal atoms, metal ions, or atomic clusters with nitrogen atoms or nitrogen ions in the gas phase.

Since nitrogen is a noncondensed phase, nitride synthesis can be controlled by the nitrogen partial pressure. A specific nitrogen equilibrium pressure, which depends on the temperature and the composition of the nitride, can be assigned to each nitride phase. The higher the stability of a nitride phase, the lower is its nitrogen equilibrium pressure. The dependence of stability [7] (free energy of formation) on temperature is shown in Figure 1.

Figure 1. Free energy of formation of various nitrides as a function of temperature (Richardson diagram) [7]
B = *bp* of metal; M = *mp* of metal; M^N = *mp* of nitride; T = transition point of metal; T^N = transition point of nitride

2. Ionic Nitrides

2.1. Lithium Nitride

The alkali metals (M) react with nitrogen to form compounds of the formula M_3N. The compound with the highest stability, and technically speaking the most interesting, is α-lithium nitride [*26134-62-3*], Li_3N [8]. This compound is a fast ionic conductor.

Figure 2. Crystal structure of lithium nitride [ionic conductivity can be attributed to the mobility of the Li (2)$^+$ ions]

Lithium nitride can be obtained by reacting lithium metal with nitrogen at >800 K. The structure of α-Li_3N (Fig. 2) is characterized by hexagonal Li_2N layers, perpendicular to the *c* axis. A lithium defect concentration of 1 – 2 % is responsible for the high mobility of Li^+ ions Li (2) in these Li_2N layers [9]; the positions of the bridging lithium atoms Li (1) between the layers are fully occupied and do not contribute to ionic conductivity. Defect formation is due to the incorporation of hydrogen and NH^{2-} groups [10]. Because of compositional differences, it is very difficult to give precise values for the ionic conductivity of lithium nitride. At 300 K, conductivity values of 1.2×10^{-3} $\Omega^{-1}cm^{-1}$ have been measured perpendicular to the *c* axis for single crystals, and 6.6×10^{-4} $\Omega^{-1}cm^{-1}$ for polycrystalline materials [11]. Important properties of lithium nitride are listed in Table 1. Compact lithium nitride can be handled easily in air but, when finely dispersed, is inflammable.

α-Lithium nitride melts congruently at 1086 K. Ruby-red single crystals can be formed by reacting molten lithium with nitrogen at ca. 0.1 MPa and 800 K, according to the Czochralski method [12]. Single crystals with a volume of ca. 10 cm^3 can be produced in this way for solid-state studies [12, 13].

Simple sintering processes can be employed to produce dense material that is used as a solid-state electrolyte in lithium batteries (Fig. 3) [14]. Lithium serves as the anode; it is separated from the cathode by lithium nitride. The cathode can be formed from a sulfide phase ($TiLi_xS_2$ or $TaLi_xS_2$) that has a high absorbing capacity for Li^+ ions. When the battery is discharged, Li^+ ions migrate from the lithium metal via the solid electrolyte lithium nitride into the sulfide phase.

Figure 3. Schematic structure of a lithium battery with a Li_3N diaphragm [11]
a) Cap; b) Anode (Li); c) Isolation; d) Electrolyte (Li_3N); e) Cathode; f) Package

Lithium nitride is also used as a catalyst for the conversion of hexagonal boron nitride (α-BN) to the cubic high-pressure modification (β-BN) [15, 16].

Table 1. Properties of lithium nitride and important covalent nitrides

Property	Li_3N	α-BN	β-BN	AlN	GaN	α-Si_3N_4	β-Si_3N_4
Structure (Pearson)	hP4	hP4	cF8	hP4	hP4	hP28	hP14

2.2. Nitrides of Alkaline-Earth Metals

Alkaline-earth metals react with nitrogen to form nitrides of the composition M_3N_2. They are used as sintering additives for special ceramics and as catalysts for the production of cubic boron nitride [17–19]. Beryllium nitride [*1304-54-7*], Be_3N_2 [20, 21], strontium nitride [*12033-82-8*], Sr_3N_2, and barium nitride [*12047-79-9*], Ba_3N_2, have been used as sintering additives for silicon nitride (Si_3N_4) and aluminum nitride (AlN) in isolated cases; however, the addition of magnesium nitride [*12057-71-5*], Mg_3N_2 [22–24], and calcium nitride [*12013-82-0*], Ca_3N_2, to aluminum nitride [*24304-00-5*] [25–27] has gained some importance. Undesirable amorphous grain boundary phases can be almost entirely prevented in Si_3N_4 ceramics by the use of Be_3N_2 or $BeSiN_2$. These compounds are, however, toxic [28]. Calcium nitride [29] and magnesium nitride [30] have been proposed as additives for electrical, copper-based contact materials, thus replacing Ag – CuO and Cu – TiN composites. These materials are used in switches and have good contact welding properties and a high abrasion resistance.

2.3. Rare-Earth Nitrides, Earth Nitrides, and Actinide Nitrides

Nitrides of the rare-earth metals and yttrium display ionic bonding; however, scandium nitride [*25764-12-9*], ScN, has properties that lie between those of the ionic nitrides and the transition-metal nitrides. Scandium nitride [31] is the only earth-metal nitride that is relatively stable under humid atmospheric conditions [32]. It has semiconductor properties [33] and has been proposed for use in solar cells [34].

Other solid-state properties of these nitrides–such as the magnetism of gadolinium nitride [*25764-15-2*], GdN [35]–have not yet been exploited technically. Some rare-earth nitrides such as cerium nitride [*25764-08-3*], CeN, have been used as sintering additives for aluminum nitride and silicon nitride [36]. The actinide mononitrides–actinium nitride, uranium nitride, plutonium nitride, and neptunium nitride–crystallize in the cubic NaCl-type lattice like the lanthanide nitrides. In contrast to rare-earth nitrides, actinides also form phases with a higher nitrogen content (e.g., U_2N_3 [*12033-85-1*] [37], Th_3N_4 [*12033-90-8*] [38]). Phases with even higher nitrogen concentrations (UN_{2-x} [*12033-83-9*] can be synthesized with pressurized nitrogen [39]. The actinide mononitrides have been proposed as nuclear fuels in high-temperature breeder reactors.

3. Covalent Nitrides

For poly(sulfur nitride), see → Inorganic Polymers, Chap. 6.

3.1. Boron Nitride

Boron nitride [*10043-11-5*], BN, crystallizes in three modifications (α, β, and γ) with a stoichiometric ratio of boron to nitrogen of 1 : 1 (→ Boron Carbide, Boron Nitride, and Metal Borides, Chap. 2.) [40–42].

1) *White, hexagonal boron nitride* (α-BN, Fig. 4 A) has a crystal structure that is related to the graphite lattice (Fig. 4 B). The stacking order of the hexagonal layers is, however, different.
2) *Cubic boron nitride* (CBN, β-BN) is a high-pressure modification. It can be produced from α-boron nitride under conditions used for diamond synthesis by employing high pressure (4 – 6 GPa and 1400 – 1700 °C) in the presence of metal or metal nitride catalysts (see Section 2.2) [43]. Pure β-boron nitride is crystal clear. At room temperature it has a high thermal conductivity but no electrical conductivity. With a Knoop hardness of ca. 4700, β-boron nitride is the second hardest solid after diamond (Knoop hardness 7000). Although β-boron nitride is metastable at atmospheric pressure, it is thermally more stable than diamond and can be used for short periods at temperatures up to 1700 K. In air, β-boron nitride is less rapidly oxidized than diamond because a boron oxide (B_2O_3) layer is formed that protects the substance from further oxidation. The structure of β-boron nitride (zinc blende structure) is shown in Figure 4 C.
3) *Hexagonal boron nitride* (γ-BN) crystallizes in the wurtzite structure. It is also a high-pressure modification.

Figure 4. Crystal structure of hexagonal α-boron nitride (A), graphite (B), and β-boron nitride (C)

The phase diagram of the boron nitride system is shown in Figure 5 [44]. Properties of α- and β-boron nitride are listed in Tables 1 and 2.

Figure 5. Phase diagram of boron nitride [44]

β-Boron nitride was first synthesized in 1957 and introduced commercially in 1969 [45,46]. It is used mainly as an abrasive grit in grinding wheels and saws (→Abrasives, Chap. 3.7.). Apart from its extreme hardness, the high thermal conductivity of β-boron nitride is also important because it increases grinding depth and speed [42]. Diamond reacts with carbide-forming elements such as iron, chromium, tantalum, and tungsten at > ca. 1200 K and is thus not suitable for grinding or machining steel; β-boron nitride is much more stable toward these elements.

Both β- and γ-boron nitride can be made into dense, polycrystalline materials (polycrystalline cubic boron nitride, PCBN) by applying high pressure and using sintering additives such as aluminum or silicon (similar to diamond). Polycrystalline cubic boron nitride compacts are somewhat softer than single crystals but have a higher fracture toughness and less orientational anisotropy. Polycrystalline β-boron nitride can be made into cutting tools with a defined cutting edge. These tools are used to work quenched and tempered steels that could previously be worked only by grinding [47].

α-Boron Nitride Layers. Various chemical vapor deposition (CVD) processes have been

Table 2. Properties of nitride ceramics.

Property	α-BN (HIP)∗	β-BN	AlN	Si_3N_4(SSN)

proposed for the production of α-boron nitride layers [48]. The starting materials are mainly volatile boron compounds (e.g., as B_2H_6 [49–51], BCl_3 [52–58], and BF_3 [59]) as well as higher boranes and organoboron compounds. These compounds are reacted with ammonia [60, 61]. Depending on reaction temperature (ca. 700 – 1500 K) and deposition conditions, the properties of the resulting α-boron nitride films can vary considerably, especially in terms of crystalline state, structure, stoichiometry, thermal conductivity, electrical resistivity, and size of the optical band gap [48]. Thus, colorless transparent, amorphous, or crystalline boron nitride films can be produced with band gaps of 3.8 – 6.2 eV and electrical resistivities ranging from 10^9 to 10^{17} $\Omega \cdot$ cm.

The chemical reaction can be assisted by use of a microwave plasma at a moderate temperature (500 – 1200 K). Amorphous boron nitride films can usually be produced with a wide range of physical properties. Physical vapor deposition (PVD) processes, including sputtering [62–64], electron-beam evaporation [65], ion-beam deposition [66–70], and the pulsed plasma method [71–73], have also been used to produce boron nitride films. The range of physical properties of these films is much greater than that of CVD films. Significant stoichiometric variations are possible, allowing production of nontransparent boron nitride layers with a boron : nitrogen ratio up to 2.5 : 1 [63, 74].

For a detailed description of both CVD and PVD, see → Thin Films.

α-Boron nitride films are important primarily in the microelectronics industry. They can be used as a source of boron for doping silicon wafers in diode production (see Fig. 6) [48]. *n*-Silicon is thermally oxidized, then locally etched (A), and coated with a boron nitride film (B). Heating in a nitrogen atmosphere causes the boron to diffuse into the *n*-silicon, which thus becomes locally *p*-conductive (C).

Electrically insulating α-boron nitride layers are also used in metal insulator semiconductor diodes [51]; as thin, transparent substrates in X-ray lithography [75–77]; as coatings to improve oxidation resistance [78] and surface hardness [67–70, 74] (see below); for electrical insulation; and for surface modification of field effect transistors as sensors for hydrogen detection [79].

Figure 6. Production of boron nitride films for integrated circuits [48]

Extremely Hard Boron Nitride Layers. Hard boron nitride layers have been produced by ion-beam deposition [66–70]. Such layers, however, cannot be designated as β-boron nitride because, in addition to tetrahedrally coordinated boron and nitrogen atoms, they also contain a number of sp^2 hybrid bonds. In analogy with the ion-beam deposition of carbon, these layers have been termed i-boron nitride [69]. Vickers hardnesses up to 30 GPa were obtained.

Pressureless deposition of β-boron nitride has been achieved but it is more difficult than that of diamond [80–82]. Activated hydrogen seems to be essential for the production of β-boron nitride from B_2H_6 and ammonia and for the production of i-boron nitride films [83]. Reaction of activated hydrogen with $(BH_2NH_2)_3$ initially leads to the deposition of β-boron nitride and amorphous boron nitride; however,

the latter is preferentially removed by the ion sputtering effect and β-boron nitride is left behind [83]. Methods used to produce β-boron nitride layers include triode ion plating: a combination of tungsten filament activation plus radiofrequency plasma CVD [80, 83–87]. Results vary significantly, however; in particular, the boron : nitrogen ratio often differs markedly from 1 : 1 [88].

β-Boron nitride layers should be used particularly when both a high degree of hardness and a high thermal conductivity are required. Applications include cutting tools for machining and milling hard alloys (particularly quench-hardened ferrous materials), for nozzles, etc. In contrast to diamond, β-boron nitride can also be used above 1100 K. In microelectronic circuits, β-boron nitride can be employed as a heat sink.

3.2. Aluminum Nitride

Production. Industrial production of aluminum nitride [*24304-00-5*], AlN, is carried out primarily in three ways [89, 90]:

1) Direct nitriding of aluminum powder at 1100 K:

$$2\,Al + N_2 \longrightarrow 2\,AlN$$

an exothermic reaction.

2) The self-propagating high-temperature synthesis (SHS) method [91] in which the heat produced during the reaction generates a self-propagating reaction front. The reaction is started by ignition at one end of the reaction and proceeds through the sample.
3) Carbothermic nitriding by endothermic reduction of Al_2O_3:

$$Al_2O_3 + N_2 + 3\,C \longrightarrow 2\,AlN + 3\,CO$$

In direct nitriding, the product must be ground to a defined grain size (this may adversely affect sintering due to the introduction of impurities). In carbothermic nitriding, grain growth is largely avoided; excess carbon must, however, be removed in a second reaction step via the formation of carbon monoxide by reaction of carbon with mildly oxidizing gases such as water vapor or carbon dioxide.

A less important production method is the reaction of aluminum chloride or organoaluminum compounds with ammonia [89] or mixtures of nitrogen and hydrogen (R = Cl or organic group):

$$R_3Al + NH_3 \longrightarrow AlN + 3\,RH$$

This reaction is used mainly in the production of aluminum nitride layers by CVD.

Properties. Aluminum nitride , the only compound known in the Al – N system, crystallizes with a wurtzite-type structure; it is nontoxic. In powder form, aluminum nitride is pale gray (due to the presence of nonreacted aluminum). In sintered or hot-pressed form it is colorless and transparent. Aluminum nitride has a melting point of ca. 3030 K at a nitrogen pressure of 5 MPa [92]. At atmospheric pressure, it evaporates quickly above 2000 K. Hot mineral acids hydrolyze aluminum nitride powder and attack compact aluminum nitride slightly. The compound is completely stable in air up to ca. 1000 K, but above this temperature it reacts with air and oxygen. Dense aluminum nitride forms a protective, amorphous aluminum oxide layer that recrystallizes at higher temperature and protects the nitride from oxidation up to ca. 1800 K [93].

Aluminum nitride has a favorable combination of physical properties that make it particularly suitable for electronic devices (Tables 1 and 2): unusually high thermal conductivity [94] combined with high electrical resistance and a thermal expansion coefficient similar to that of silicon (to avoid thermal stress) [95]. Because of the continuing miniaturization of electronic components, efficient aluminum nitride heat sinks are necessary as substrates (packages) for heat dissipation; conventional aluminum oxide ceramics can no longer meet the requirements. In addition, chip capacities are continually increasing, which necessitates the appropriate choice of materials with thermal expansion coefficients that closely correspond to that of silicon.

Production of Aluminum Nitride Ceramics. Depending on the particle size of the aluminum nitride powder, sintering without pressure produces a material with a porosity of ca. 15 – 30 % [96–98]. Complete compaction can

be achieved only with pressure sintering processes such as hot axial pressing or hot isostatic pressing, as well as liquid-phase sintering with additives (mainly CaO, Y_2O_3, CeO_2, and ZrO_2) [25, 99, 100]. With aluminum nitride, these additives form lower-melting phases at the grain boundaries that accelerate pore removal and compaction and allow full densification exceeding 99 %. With calcium oxide, the aluminates $CaO \cdot 2\,Al_2O_3$ and $3\,CaO \cdot 5\,Al_2O_3$ can be detected at the grain boundaries of aluminum nitride. However, an oxinitride phase also seems to be formed as an intermediate in the sintering process. Magnesium oxide is unsuitable for the dense sintering of aluminum nitride [92]. The additives usually produce slight changes in its desired properties. If these cannot be tolerated, pressure sintering methods without additives must be used (see Section 3.4). Completely dense aluminum nitride can be obtained at 2100 K under a static axial pressure of 20 MPa in 30 min [92]; however, oxygen present in the starting powder reacts to form an Al – O – N phase with a spinel structure [101]. The aluminum oxinitride has interesting isotropic physical properties (transparency) as well as good chemical stability [101–103]. Aluminum nitride components can be used in air up to 1700 K. They are not wetted by metal melts. Sheet casting is a technologically important production method for aluminum nitride ceramics [104]. It is particularly suitable for the production of thin sintered parts with complicated pierced shapes and for the production of multilayer ceramic composites. In the "doctor blade" technique, aluminum nitride powder is suspended together with plasticizers in an organic solvent (e.g., gasoline, a ketone, toluene, or a mixture of these), drawn to a sheet, and cut to the desired length at a speed of ca. 30 cm/s.

Uses. The following properties of aluminum nitride are important for the electronics industry: high thermal conductivity, a thermal expansion coefficient similar to that of silicon, and high strength (Table 2). These properties are necessary for the development and use of efficient microelectronic circuits such as very large-scale integrated circuits (VLSI). Aluminum nitride substrates (also known as packages) are also used as coolers for power transistors, integrated circuits, laser diodes, thyristors, and ceramic dual inline packages (Fig. 7) [105].

The fact that aluminum nitride is not wetted by metals is taken advantage of in the melting and casting of dental alloys. The crucible surface is coated with aluminum nitride to prevent the diffusion of impurities from crucible materials into the alloys. The high modulus of elasticity of fully dense aluminum nitride combined with its low density make it a suitable material for lightweight personal armor (bullet-proof vests).

Figure 7. Aluminum nitride substrate ceramics with gold pins for silicon sensors (ANCERAM, Bindlach, FRG)

3.3. Gallium Nitride

Production and Properties. Gallium nitride [*25617-97-4*], GaN, can be produced by heating gallium in a stream of ammonia at 900 – 1200 K [106]:

$$2\,Ga + 2\,NH_3 \longrightarrow 2\,GaN + 3\,H_2$$

Heating in molecular nitrogen at atmospheric pressure fails to give the desired product; very high pressure would have to be applied because of the high nitrogen equilibrium pressure of gallium nitride [107, 108]. Hence, the production of compact samples and single crystals (important for solid-state investigations, particularly electronics) is very difficult. The nitriding of gallium and gallium nitride with ammonia yields crystals with dimensions of ca. 5×0.3 mm and 5×1 mm, respectively [109, 110]. Thin gallium nitride layers have been produced by CVD [111–113], liquid-phase epitaxy [114], and molecular-beam

epitaxy. Chemical vapor deposition is based on the following reaction [111–113, 115–118]:

$$GaCl_3 + NH_3 \longrightarrow GaN + 3\,HCl$$

Satisfactory crystal nucleating substrates on which gallium nitride can grow epitaxially have not yet been found [119]. Either the crystal lattice fit is not good enough (e.g., Al_2O_3, Si) or the chemical resistance is unsatisfactory (e.g., HCl attack in the case of ZnO).

Gallium nitride crystallizes in the wurtzite-type structure (a cubic modification has also been described [120]) and in its compact form is colorless; it can, however, assume orange to yellow shades depending on the impurities or doping agents (e.g., Mg, Zn) [111]. Gallium nitride is almost completely stable to acids but dissolves in hot alkaline solutions. It is stable to oxidation in air up to ca. 1100 K.

Gallium nitride is a semiconductor with a band gap of 3.48 eV at 4.2 K [121]. However, its electronic properties such as carrier concentration and electrical resistance are highly dependent on the method of preparation [122–124].

Uses. Gallium nitride has been used commercially as a light-emitting diode (LED) only since 1985, although its suitability for this purpose was discovered in the early 1970s [123, 125–127]. Gallium nitride LEDs are used in medicine; they emit blue light, which is used to induce fluorescence in blood pigments for analytical purposes.

Other potential uses of gallium nitride (e.g., in microwave amplifiers and as a material for switching contacts [128]) have not been exploited commercially. Applications of gallium nitride are likely to increase in the near future, particularly if pure gallium nitride materials with defined properties can be produced.

3.4. Silicon Nitride

During the last twenty years, silicon nitride [*12033-89-5*], Si_3N_4, has become an extremely important material for structural ceramics owing to its excellent high-temperature properties, its stability to oxidation, its high fracture toughness, and its low thermal expansion coefficient (Table 2) [129–135]; see also → Ceramics, Advanced Structural Products, Chap. 3.3. Heat engines with silicon nitride parts show improved efficiency because a higher operating temperature can be employed.

Structure. Silicon nitride crystallizes in two modifications (α- and β-Si_3N_4) that differ with regard to the stacking order of the SiN_4 tetrahedral layers [136]. The β-form has a phenacite-type structure (Be_2SiO_4) and the stacking order AB, AB, etc. In the α-form the AB order is followed by a mirror image, which results in the stacking pattern ABCD, ABCD, etc., and an elementary cell twice as large as that of β-silicon nitride. Both modifications can exchange silicon and nitrogen atoms for other atoms without structural changes.

α-Silicon nitride is usually formed at < 1700 K; above this temperature, it is irreversibly converted to the β-form [137]. α-Silicon nitride is obtained mainly in the form of fibers and whiskers during the nitriding of silicon at lower temperature. β-Silicon nitride is formed primarily by reaction of nitrogen with pure silicon or silicon alloys at high temperature [138].

α-Silicon nitride forms mixed phases by the partial substitution of Si^{4+} with Al^{3+} and simultaneous incorporation of metal cations (e.g., Li^+, Ca^{2+}, Mg^{2+}, and rare-earth metals [139, 140] or by the partial replacement of N^{3-} with O^{2-}. The phases that are isotypic to α-silicon nitride (α'-phases) can be defined by the following formula:

$$M_xSi_{12-(m+n)}Al_{(m-n)}O_nN_{16-n}$$

where $x < 2$; purely nitridic phases (without oxygen) are also possible [141].

In β-silicon nitride, Si^{4+} can be replaced by Al^{3+} (or Y^{3+} and Be^{2+}); to ensure charge compensation, N^{3-} can simultaneously be replaced by O^{2-}. The substitution of aluminum for silicon occurs fairly easily because of the close coordination symmetry of the two elements [142] and yields the sialons (SiAlONs) [142–146] with the general formula:

$$Si_{6-x}Al_xO_xN_{8-x}$$

$x < 2$ at 1670 K and 4.2 at 1970 K [142].

The physical properties of sialons resemble those of β-silicon nitride, but the chemical properties resemble those of corundum. The thermal expansion and thermal conductivity of sialons are lower than those of β-silicon nitride; their stability to oxidation and high-temperature strength are greater. Sialons can be sintered without pressure [147]; at 2000 – 2100 K they react with sintering additives such as yttrium oxide (Y_2O_3) or magnesium oxide (MgO) to form liquid phases that are less viscous than silicon nitride. Thus, sintering to full density is easier than with silicon nitride ceramics.

The production methods and applications for sialon parts are similar to those of silicon nitride. Sialons were the first nitride ceramics to be used commercially [142]. High-temperature ball bearings, indexable inserts (for the machining of cast-iron and nickel-based superalloys), and high-temperature dies are made from sialons. The applications of sialons are expected to increase substantially.

Production of Silicon Nitride Powder. Silicon nitride is a white powder that can be produced in four ways [90]:

1) Nitriding of silicon powder [148, 149]:

$$3\,Si + 2\,N_2 \longrightarrow Si_3N_4$$

2) Chemical vapor deposition of silicon chloride or chlorosilanes in the presence of ammonia or an $H_2 - N_2$ mixture [90, 149–154]:

$$3\,SiCl_4 + 4\,NH_3 \longrightarrow Si_3N_4 + 12\,HCl$$

3) Carbothermic reduction of silicon(IV) oxide in the presence of nitrogen [149, 155–157]:

$$3\,SiO_2 + 6\,C + 2\,N_2 \longrightarrow Si_3N_4 + 6\,CO$$

4) Precipitation and thermal decomposition of silicon diimide [90]:

$$SiCl_4 + 6\,NH_3 \longrightarrow Si(NH)_2\downarrow + 4\,NH_4Cl$$
$$3\,Si(NH)_2 \longrightarrow Si_3N_4 + 2\,NH_3$$

These methods yield products with widely different properties. Silicon nitride powder that is produced by nitriding silicon must be comminuted and the impurities introduced during comminution must be removed by leaching. Important factors for further processing are the specific surface area (generally regarded as a criterion for the sintering activity of the powder) and the content of nonmetallic (O, C) and metallic (Fe, Al, Ca) impurities. Other criteria include the crystallinity, the ratio of α- and β-forms, and the morphology of the powder particles. An oxygen content of ca. 1 – 2 wt % is advantageous because the silicon dioxide layer on the silicon nitride particles substantially promotes sintering. In contrast, the presence of carbon leads to the decomposition of oxides and impairs sintering.

Sintering of Silicon Nitride. Silicon nitride is a covalently bonded compound with very strong interatomic bonding forces, which makes nitrogen diffusion a very slow process [158]. Thus, sintering of silicon nitride without pressure by self-diffusion alone is virtually impossible. The temperature necessary to accelerate diffusion is markedly higher than the decomposition temperature of silicon nitride at normal pressure (2200 K at 0.1 MPa N_2) [28]. decomposition must be counteracted by a high nitrogen pressure [28, 159].

Four important processes for the production of silicon nitride sintered parts are:

1) Reaction bonding with and without final sintering (reaction-bonded silicon nitride, RBSN);
2) Pressureless sintering (sintered silicon nitride, SSN);
3) Hot pressing (hot-pressed silicon nitride, HPSN); and
4) Hot isostatic pressing (isostatically pressed silicon nitride, IPSN).

Reaction bonding with sintering makes use of the fact that preforms made of silicon powder can be converted into reaction-bonded silicon nitride parts (RBSN) without dimensional changes. The preforms are heated in nitrogen until complete nitriding of silicon has occurred. The preforms are produced by conventional methods such as slip casting, injection molding, or isostatic pressing. After evaporation of plasticizing and pressing additives, the preform is heated in a nitrogen atmosphere. Nitriding begins at ca. 1300 K, and the temperature must not exceed 1680 K (the melting point of silicon).

A 22 % volume increase occurs during nitriding and the pores are thus partially filled [160]. The advantage of this method is that the dimensions of the preforms are closely retained, with no danger of distortion or crack formation. The high temperature strength of the product is advantageous because additives are not required, but stability to oxidation is reduced by the large surface area. Its primary disadvantage is that the maximum obtainable density is only ca. 90 % of the theoretical value [161].

Reaction-bonded silicon nitride can be cheaply redensified by resintering (the sintered reaction-bonded silicon nitride SRBSN process) in which sintering agents are admixed to the silicon powder. The other processing steps are analogous to the production of RBSN; however, additional thermal treatment is necessary.

Pressureless sintering has a potentially wide range of industrial applications [162–165]. Additives can be added to the starting powder. The additives react with the silicon dioxide layer on the silicon nitride particles to form a lower-melting silicate phase in which redissolution leads to the precipitation of β-silicon nitride in the form of rods [166]. The morphology of the precipitated β-phase has a favorable influence on the mechanical properties of the product. Oxide sintering additives include MgO, Y_2O_3, CeO_2, ZrO_2, and Al_2O_3. Nonoxide additives are mainly nitrides composed of two elements (e.g., Mg_2N_3, AlN, TiN, ZrN, and CrN). Sintering is carried out at ≤ 2150 K and atmospheric pressure, or at 2400 K and increased pressure (1 – 2 MPa) [163–165, 167].

Sintered silicon nitride (SSN) contracts by ca. 15 % on sintering but has no structural anisotropy. The strength of the sintered part decreases at > 1300 K due to formation of a glass phase. Subsequent thermal treatment leads to partial crystallization of the amorphous grain boundary phase and thus increases the strength [168].

Hot pressing of silicon nitride is carried out mainly in graphite dies at $\leq$ 2100 K and ≤ 50 MPa. Silicon nitride raw material with additives is used (see above), and fully dense sintered parts can be obtained after a pressing time of 10 min. The elimination of pores by the capillary forces acting during the sintering and diffusion processes is enhanced by the applied pressure. The disadvantages of hot pressing are that only geometrically simple forms can be produced and expensive finishing processes with diamond wheels are necessary. Hot-pressed silicon nitride has a directionally dependent strength, with typical values of ca. 850 MPa.

Hot isostatically pressed (HIP) silicon nitride is produced by subjecting powder compacts or presintered silicon nitride parts to the simultaneous action of gas pressure (< 200 MPa) and high temperature (> 2000 K). This process effectively eliminates closed porosity [169]. In the case of open porosity, the sintered part must be encapsulated before being pressed. Refractory metals, highly viscous glasses [170], or sintered layers of ceramic powders (possibly with intermediate BN layers) [171] are used as encapsulating materials and must be removed after the HIP process. The disadvantages of this method lie in the extreme process conditions and the difficulty of encapsulating geometrically complicated parts. In the sinter-HIP process the material is presintered at atmospheric pressure to a density of up to 94 %, tantamount to closed porosity. A completely dense material is obtained in the same furnace run by subsequently increasing the pressure to ca. 10 MPa. The production costs of this sinter-HIP process are lower than those of the HIP process.

Properties and Uses of Silicon Nitride Ceramics. In 1988 ca. 200 – 250 t of silicon nitride ceramic parts were produced worldwide. These ceramics are characterized by relatively high strength and toughness values, a low thermal expansion coefficient, high thermal conductivity, and high thermal shock resistance (Table 2). The strength remains unchanged at high temperature and surpasses that of the best superalloys above 1400 K. Stability to oxidation is excellent. The materials are also stable to combustion gases containing sulfur and halogens.

The properties of silicon nitride ceramics depend on their microstructure, e.g., grain boundary content, glass phase content, type and amount of additive, production method, and porosity.

Because of its properties, silicon nitride is used in heavy-duty components in automotive engines (e.g., precombustion chambers, cylinder linings, turbochargers, and piston heads) [172]. As early as 1985, silicon nitride turbochargers were used in automobiles in Japan [173]. They

permit the use of higher temperature and thus improve the efficiency of fuel utilization. They also reduce engine weight and structural complexity because cooling equipment is unnecessary. Steel ball bearings can be operated only up to 620 K [174]. By contrast, silicon nitride bearings can be used up to 1100 K, even in highly corrosive atmospheres and media (e.g., HCl, H_2SO_4) [175, 176]. Silicon nitride ceramics are also used in high-performance pressure valves and diffusion nozzles, e.g., in carbon hydrogenation and ammonia synthesis [177]. In addition, they have applications in metalworking (e.g., cutting tools, drawing dies, and cutting torch nozzles) [178].

Silicon nitride layers are used as diffusion barriers and passive coatings in semiconductor components [179]. They are produced by reaction of silicon tetrachloride with hydrazine [180] or by physical vapor deposition [181].

3.5. Miscellaneous Covalent Nitrides

The remaining nitrides of the main group elements are interesting primarily because of their semiconductor properties. They can be produced either by nitriding the elements with nitrogen at high pressure or by reaction in a stream of ammonia. Indium nitride [*25617-98-5*], InN [108, 182, 183], has been proposed as a semiconductor layer for field effect transistors (FETs) and metal – alumina – nitride – semiconductor (MANS) diodes [184, 185]. Thermal nitriding of indium phosphide (InP) wafers by reaction with ammonia at ca. 800 K gives a thin (ca. 5 – 10 nm) indium nitride layer.

Germanium nitride [*12065-36-0*], Ge_3N_4, is thermally unstable [186]. Semiconductor layers of germanium nitride on gallium arsenide (GaAs) are important for the production of metal insulator semiconductors [187, 188]. Amorphous tin [*55574-97-5*], lead [*52036-89-2*] [189–191], and antimony [*12333-57-2*] [192] nitrides have been studied as transparent, electrically conducting films for electrooptical purposes.

Layers of phosphorus nitride [*12136-91-3*], P_3N_5, can be produced by the reaction of phosphine (PH_3), ammonia, and nitrogen at < 1200 K; they are of interest for electronic microtransistors [193].

4. Transition-Metal Nitrides

Transition-metal nitrides attracted interest at an early stage because of their striking properties such as hardness, metallic luster, and color [5]. They are less thermally stable than carbides but resemble them in many ways (→Carbides). Only the nitrides of the group 4 metals titanium, zirconium, and hafnium melt at a nitrogen pressure of 1 MPa without decomposition.

4.1. Production

Transition-metal nitrides can be produced according to the methods specified in Chapter 1; however, precise knowledge of the thermodynamic data of nitrides is necessary [194]. The thermodynamic stability of nitrides decreases with increasing group number; hence, the nitrides of higher group numbers ($\geq$ group 6) can be prepared only by nitriding with nitrogen at high pressure or by nitriding in a stream of ammonia gas. Thus, titanium nitride, zirconium nitride, and hafnium nitride are the most stable nitrides with the lowest nitrogen equilibrium pressures.

Nitride formation with group 4 and 5 metals is exothermic. The heat released during the reaction of metal powder with nitrogen gas can be sufficient to reach the melting temperature of the metal. This is undesirable for the industrial production of nitride powders because the dense-sintered or molten metal reguli (metallic mass formed at the bottom of the vessel) do not react completely with nitrogen; hence, the desired fine-grained nitride powder is difficult to obtain from the reaction products by comminution.

Reaction of metal oxides with carbon and nitrogen yields nitrides containing oxygen and carbon. Reaction of a very fine-grained stoichiometric mixture of titanium(IV) oxide and carbon in the presence of nitrogen can yield titanium nitride with a low oxygen and carbon content and with properties favorable for the use of titanium carbonitride hard metals (cermets) [195].

High-temperature annealing, usually at increased nitrogen pressure, is employed to produce granular or single-crystal nitrides [196, 197]; zone drawing and zone melting methods

are used for the production of large single crystals [198–200]. In zone melting the nitrogen pressure should be kept at levels high enough to prevent both decomposition of the nitride and formation of heterogeneous compounds with a low stoichiometry.

Single crystals of transition-metal nitrides can also be produced by crystallization from fluxes [201–203] and CVD [204]. Flux growth exploits the fact that nitrides are soluble in metal melts and that coarsely crystalline samples and single crystals can be obtained by cooling or crystal extraction.

Volatile chlorides of the transition metals can be employed to advantage in the CVD reactions:

$$TiCl_4 + 1/2\,(1-x)\,N_2 + 2\,H_2 \longrightarrow TiN_{1-x} + 4\,HCl$$

The CVD process is used mainly to coat cutting tools with thin nitride layers (see Section 4.3.1).

Physical vapor deposition and ion-assisted deposition (IAD) utilize the recombination of metal atoms or metal ions with nitrogen in the gas phase to deposit nitride layers [205]. The metal targets are either subjected to cathode sputtering or to evaporation in an arc plasma or by an electron beam. The metal ions or atoms recombine with nitrogen at low pressure, preferentially on the surface of solid "substrates". The properties of the resulting nitride layers are highly dependent on sputtering conditions [206–211].

4.2. General Properties

Data for transition-metal nitride systems are still lacking, the known phases are listed in Table 3. In addition to the technically important mononitride phases with their very wide range of phase composition with respect to nitrogen content (made explicit in the notation by a free parameter, e.g., TiN_{1-x} [*11116-16-8*]), several other phases often exist with a lower nitrogen content and a narrower range of composition. Some nitride phases may contain more nitrogen atoms than metal atoms (e.g., Nb_4N_5 [*12594-34-2*] [212] and Ta_3N_5 [*12033-94-2*] [213]).

Within the homogeneity range, virtually all physical, chemical, and mechanical properties of the nitride phase are subject to continuous change. Deviations from "ideal" stoichiometry can, however, lead to the formation of states of order in the partial metalloid lattice [214, 215] that cause distortion and hence a reduction of symmetry. The crystal structures of binary transition-metal nitrides are generally close-packed (face-centered cubic, hexagonal close-packed, tetragonal close-packed) arrays of the larger metal atoms, with the smaller nitrogen atoms in the interstitial voids [41].

Table 3. Known phases of binary transition-metal nitrides ∗

Nitride	Phases
Ti – N	ε-Ti_2N (t), η-Ti_3N_{2-x} (r), ζ-Ti_4N_{3-x} (r), δ'-$TiN_{0.5}$ (t), δ-TiN_{1-x} (c)

∗ Crystal system: c, cubic; h, hexagonal; t, tetragonal;o, orthorhombic; r, rhombohedral (trigonal).

The technically useful "mono" nitrides, TiN_{1-x}, ZrN_{1-x}[*119173-61-4*], and HfN_{1-x} [*11115-87-0*], crystallize in the sodium chloride-type lattice. The high-temperature phases of the mononitrides niobium nitride (NbN) and tantalum nitride (TaN) also crystallize with the sodium chloride structure [216–219]. However, these mononitrides undergo phase transitions to modifications with more complicated structures in which nitrogen may not be octahedrally coordinated.

Transition-metal nitrides exhibit metallic character but, in contrast to metals, are brittle and usually very hard. They have high thermal and electrical conductivities as well as a metallic luster. The mononitrides even display superconductivity.

Transition-metal nitrides can form solid solutions with other isotypic nitrides, carbides, and oxides. They are wetted by liquid metals, particularly those belonging to the iron group, if the oxide surface layer that inhibits wetting can be decomposed or removed. Transition-metal nitrides are highly resistant to acid corrosion at room temperature; however, they are slowly dissolved by hot acid and rapidly dissolved by hydrofluoric acid. Stability to oxidation is comparable to that of carbides. The technically most important properties of transition-metal nitrides are listed in Table 4 [220–234].

4.3. Uses

The uses of transition-metal nitrides exploit their properties (hardness, wear resistance, chemical resistance, stability to oxidation, resistance to diffusion of metals, and color).

4.3.1. Wear-Resistant Layers

Most tools for metal cutting are coated with hard materials to reduce wear on the edge of the cutting tool, to prolong tool life, or to increase the cutting speed. These thin ($< 10\,\mu m$) but effective coatings (Fig. 8) should be hard and chemically inert to the material of the running chip moving across the rake face of the cutting tool. They should also adhere well to the substrate and have a thermal expansion coefficient similar to that of the substrate.

Transition-metal nitrides, especially titanium nitride but also zirconium and hafnium nitrides, are particularly suitable for reducing the wear on cutting tools (mainly steel or hard metals).

Use is made of the fact that the nitrides have a lower frictional welding tendency at the tool – workpiece interface compared to that of the uncoated cutting tool (e.g., steel). The adhesive properties of transition-metal nitrides are similar to those of carbides; however, the latter are superior in terms of hardness.

Three processes are employed for applying wear-resistant layers:

1) Chemical vapor deposition (CVD)
2) Physical vapor deposition (PVD)
3) Case hardening in a nitriding bath or with a plasma

CVD and PVD Nitride Layers. For a detailed description of CVD and PVD, see → Thin Films. The CVD of nitrides primarily employs the reaction of volatile chlorides with nitrogen – hydrogen mixtures in the gas phase at a substrate temperature of ca. 1300 K. In PVD processes, however, a temperature of ca. 800 K is used [205, 235].

In ion plating (PVD), the metal component is evaporated (e.g., with an electron beam or electric arc) and reacts with nitrogen ions formed in a low-pressure glow discharge; the resulting nitride is precipitated on the substrate. Because of the low substrate temperature ($< 560\,°C$) high-speed steel tools can be coated below their softening temperature. Sputtering and ion plating are carried out at low pressure where the reactive particles are mainly propagated in straight lines. Development of shadowing effects must therefore be prevented by turning the substrate parts during the coating process.

Both CVD and PVD processes produce layers [often a combination of different hard-material layers such as TiN, TiC, Ti(C,N), and Al_2O_3] [236, 237] with a thickness of ca. 5 – 10 µm. Thicker layers on tools are used for continuous cutting (e.g., carbide tips for turning on a lathe); thinner layers, for interrupted cutting (milling machine).

Layers deposited by CVD are much closer to thermodynamic equilibrium than those obtained by PVD [238]. Thus, the physical and mechanical properties of the PVD layers often differ substantially from those of compact nitrides [239,

Table 4. Properties of metal nitrides in bulk form (groups 4 – 6)

240], whereas CVD layers have comparable properties [241, 242]. The PVD layers are more finely grained, are usually subject to compressive stresses, and have a higher degree of hardness up to ca. 1300 K; these factors improve wear resistance. Above ca. 1300 K the hardness values of PVD and CVD layers become similar due to thermally induced rearrangement and recrystallization. The room-temperature Vickers hardnesses (50-g load) of PVD and CVD titanium nitride layers are ca. 2400 and 1800 kg/mm^2, respectively; corresponding values for hafnium nitride layers are 3000 and 1200 kg/mm^2 [239].

Layers produced by PVD have large lattice defect concentrations that affect their mechanical properties [243]. The adhesive strength of CVD layers is usually excellent, due to the high substrate temperature and the reactive components in the gas phase (HCl). However, in coating WC – Co hard-metal tools decarburization may occur at the interface between the carbide substrate and the nitride layer, resulting in a deterioration of edge strength. The cutting edges of hard-metal indexable inserts are therefore rounded or chamfered prior to CVD coating.

Layers of TiN and Ti (C, N) are used particularly for indexable inserts in steel cutting tools and for dies. The trend is toward multilayer coating for metal cutting tools. Because of their striking color, layers of TiN, Ti (C, N), ZrN, and Hf N are used for decorative purposes and for increasing hardness (scratch resistance) of jewelry (e.g., watch cases).

Internationally, ca. 70 % of all hard-metal tools are currently used in the as-coated condition. In Europe, ca. 650×10^6 indexable inserts coated with hard materials are produced, most of them being coated with titanium nitride.

Nitride Layers Produced by Case Hardening. Nitride hardening of materials [244, 245] is carried out by reacting the material surface with nitrogen to produce a hard, wear-resistant layer (case) (→ Metals, Surface Treatment, Chap. 4.2.2.). Hard, corrosion-resistant Fe_3N and Fe_4N layers as well as ternary iron carbonitrides are formed on steel surfaces by methods such as ammonia, plasma, and salt-bath nitriding. The formation of various nitrides and carbonitrides of the alloy components of alloyed steels has been reported [e.g., VN, Cr_2N, CrN, Ni_3(C, N), Mn_4N, and Co_3N] [246]. These improve the mechanical properties of the surface of the material (precipitation hardening). Case hardening has the advantage that the treated items do not become distorted, unlike quench hardening which usually results in small dimensional changes or even distortions. In the nitriding of titanium alloys, the strength and increased hardness of titanium nitride are exploited [247, 248].

Flame spraying and plasma spraying methods are not used to produce wear-resistant nitride layers because the nitrides decompose at high temperature [249, 250].

4.3.2. Cermets

Since the 1970s, titanium nitride and titanium carbonitride have become particularly important as hard components in tungsten carbide-free hard metals [251] (cermets [252]).

The term "cermet" originally denoted all composites consisting of a ceramic material embedded in a metal matrix. Its meaning has recently been narrowed down, at least in the hardmetal industry, to denote sintered composite materials consisting of hard ceramic component(s) [TiC, TiN, or Ti(C, N), with Mo_2C, WC, and other carbides as additives] and a metal binder (Ni, Ni – Mo, or Ni – Co – Mo) [253–256]; see also → Ceramics, Ceramic – Metal Systems, Chap. 6.1.

Solid solutions of (Ti, Mo) (C, N) or (Ti, W) (C, N) tend to decompose on cooling into two isostructural phases α' and α''; the α'-phase is rich in nitrogen and titanium, whereas the α''-phase is rich in carbon and molybdenum (tungsten). In liquid-phase sintering [257], this effect (spinodal separation) produces hard particles consisting of a molybdenum-rich (Ti, Mo)C rim and a nitrogen rich Ti (C, N) core (Fig. 9). The rim is easily wetted by the binding metal, whereas the core has excellent wear resistance.

Sintering and diffusion mechanisms in cermets are still not well understood [258]. The specific grain structure can be obtained not only by spinodal decomposition of a homogeneous solid solution but also if titanium nitride (TiN), titanium carbide (TiC), molybdenum carbide (Mo_2C), or tungsten carbide (WC) are used as starting materials in cermet production. Nitrogen seems to displace molybdenum from the

core of the hard grain to the periphery and thus improves adhesion of the grain in the binder. A development is the addition of ternary nitrides and carbides to the powder mixture [256].

Figure 9. Typical core and rim structure in a Ti (C, N) cermet (TTI, Krupp WIDIA, Essen, FRG)
Dark areas (core) are composed of Ti (C, N), gray areas (rim) of (Ti, Ta, Mo, W) C_{1-x}, and light areas of the matrix alloy.

In Japan, 30 % of the conventional hard metals for metal cutting have been replaced by cermets; the annual growth rate is ≤ 5 %. In the machining of steel with low chip cross-sections, cermets are superior to the conventional WC – TiC – TaC – Co hard metals in terms of holding time and cutting speed and especially when high surface quality is required. Furthermore, cermets are only ca. one-third as dense as WC – Co hard metals.

4.3.3. Other Uses

Some of the more stable transition-metal nitrides such as titanium nitride, TiN [259–261], zirconium nitride, ZrN [262, 263], hafnium nitride, HfN [264], and tantalum nitride [*12033-62-4*], TaN [265, 266], are used as diffusion barriers in semiconductor technology [267, 268]. Their suitability for this application was recognized when the addition of nitrogen [269] improved the properties of Ti–W alloys [270]. The metallization of integrated circuits is required for attaching beam leads [260] to semiconductor components [268], in solar cells [271, 272], for heat sinks, and for protection against atmospheric effects. Semiconductors such as silicon [265] and gallium arsenide (GaAs) [273, 274] are coated with metals such as aluminum, gold, nickel, titanium, and palladium. Diffusion barriers are required to prevent the undesirable formation of intermetallic phases between the semiconductor and the metallized layer [275]. The material of the diffusion barrier must meet the following requirements [265, 276]:

1) High thermodynamic stability, no reaction with metals such as silicon, copper, gold, nickel, palladium, and platinum;
2) High diffusion resistance to these metals;
3) Good adhesive properties;
4) Low ohmic resistance; and
5) Good thermal conductivity.

The diffusion barriers are formed with a thickness of ca. 100 nm by reactive sputtering. Compositions (e.g., nitrogen and oxygen content) can be varied and affect the properties of the barrier [261, 277].

Other potential uses of transition-metal nitrides are found mainly in electronics and optics. Titanium nitride has been proposed for the surface treatment of windows in microwave technology [278] and as a metallization layer on aluminum nitride ceramic substrates; titanium nitride, tantalum nitride, zirconium nitride, and hafnium nitride have been suggested as heat reflectors [279, 280]; and tantalum nitride has potential use as a protective layer for moisture sensors [281]. Attempts to apply iron nitrides [282–284] (Fe_4N has a Curie temperature of > 800 K [285]) and cobalt nitrides [286, 287] as magnetizable compounds in powder form or as layers for magnetic storage are also promising.

The superconductive properties of cubic phases [288], especially of zirconium nitride, ZrN [289–291], vanadium nitride, VN [228], niobium nitride [*24621-21-4*], NbN [292, 293], and molybdenum nitride [*12033-19-1*], MoN [234, 294–300], have been studied. Mixed crystals of nitride pairs can have minimum (e.g., NbN – VN) or maximum (e.g., NbN – TiN) transition points [288].

The use of ZrN, Zr_3N_4, and NbN has been suggested for Josephson junctions in fast computers [289]; the special resistance of the NaCl-type nitrides to radiation [301, 302] could lead to applications in nuclear fusion reactors [303].

4.4. Multicomponent Nitrides

Metal atoms, which otherwise only form covalent nitrides, have been integrated into binary transition-metal nitrides by using PVD to synthesize substances that are not in thermodynamic equilibrium.

An interesting development in the area of multicomponent nitrides is the production of (Ti, Al)N and (Ti, V, Al)N layers [304–306]. Magnetron sputtering (a PVD process) has been used to obtain metastable ternary Ti – Al – N and quaternary Ti – Al – V – N layers with good wear resistance (e.g., for indexable inserts) [307]. The face-centered cubic structure of these metastable materials remains unchanged even after annealing.

A similar technological potential can also be anticipated for Ti – B – N and Ti – C – B – N layers [308] with degrees of hardness up to 50 GPa on the Vickers scale. Very hard sandwich films can be obtained with alternating titanium nitride and vanadium nitride layers (thickness 0.8 – 16 nm) [309].

An interesting modification of β-boron nitride formation is the deposition of quaternary Ti – C – B – N layers [87, 88]. A comparison of Ti – B – N and Ti – C – B – N layers with Ti – B and Ti – C – B layers indicates a marked increase in the degree of hardness (Vickers hardness up to 60 GPa) due to the incorporation of nitrogen.

Rapid development may be expected in the field of PVD because of the large range of available techniques and the possibilities of combining different materials.

1. Introduction

Organic compounds containing the – CN group are generically called nitriles. The term "nitrile" refers to the triply bound nitrogen atom, ≡N, and not to the carbon atom attached to it; therefore numbering of the aliphatic chain starts with that carbon atom (e.g., 4-chlorobutyronitrile describes the chemical formula $ClCH_2CH_2CH_2CN$). Nitriles R – CN are usually viewed as derivatives of the corresponding acids R – COOH. Consequently, they are also named by changing the ending "ic acid" or "oic acid" to "onitrile" (e.g., glutaric acid → glutaronitrile; dodecanoic acid → dodecanonitrile, propiononitrile, as an exception, is commonly referred to as propionitrile). Another way of naming nitriles is to state the name of the group R and use the prefix "cyano" or the suffix "cyanide" (e.g., cyanoethane and ethyl cyanide both describe H_3CCH_2CN). Nitriles that are obtained by addition of hydrogen cyanide to ketones or aldehydes and thus have both a hydroxy and a cyano group attached to the same carbon atom are commonly termed cyanohydrins (e.g., acetone cyanohydrin is identical to 2-hydroxy-2-methylpropionitrile). The same nomenclature applies to 3-hydroxypropionitrile which is commonly named ethylene cyanohydrin.

2. Aliphatic Nitriles

Aliphatic nitriles are important starting materials for polymers as well as for the synthesis of e.g., pharmaceuticals and pesticides.

2.1. Physical Properties

The carbon – nitrogen bond is extremely polar, which results in nitriles having a high dipole moment. This large dipole moment leads to intramolecular association; hence, nitriles have higher boiling points than would be expected from their molecular mass. Most of the lower molecular mass aliphatic nitriles (up to $C_{13}H_{27}CN$) are liquids at room temperature.

Table 1. Physical properties

Nitrile	M_r	*mp*, °C	*bp* (101.3 kPa), °C	n_D^{20}	d_4^{20}
Acetonitrile, CH_3CN	41.05	− 45	81.6	1.3441	0.7138
Propionitrile, CH_3CH_2CN	55.08	− 93	97.2	1.3670	0.782
Butyronitrile, $CH_3CH_2CH_2CN$	69.10	−111.9	116 – 117	1.3838	0.7936
Valeronitrile, $CH_3CH_2CH_2CH_2CN$	83.13	− 96	141.3	1.3971	0.8008
Tetradecanonitrile, $CH_3(CH_2)_{12}CN$	209.38	19.25	226 (10 kPa)	1.4392 [a]	0.8281 [d]
Malononitrile, $NCCH_2CN$	66.06	30 – 31	218 – 219	1.4146 [b]	1.0494 [e]
Succinonitrile, $NCCH_2CH_2CN$	80.09	57	265 – 267	1.4173 [c]	0.9867 [c]
Glutaronitrile, $NC(CH_2)_3CN$	94.12	− 29	286	1.4295	0.9911 [f]
Allyl cyanide, $CH_2{=}CH-CH_2CN$	67.09	− 84	119	1.4060	0.8329
Methyleneglutaronitrile, $NCC_2H_4C(=CH_2)CN$	106.12	− 9.0	113 (0.66 kPa)	1.4558	0.9831 [f]

Measuring temperature: [a] 25 °C; [b] 34 °C; [c] 60 °C; [d] 19 °C; [e] 35 °C; [f] 15 °C.

Simple nitriles such as acetonitrile, propionitrile, glycolonitrile, and malononitrile are miscible with water; the latter two having a higher solubility because of the presence of two polar groups. Nitriles with higher molecular mass are sparingly water-soluble. Nitriles are good solvents for both polar and nonpolar solutes. The physical properties of selected nitriles are listed in Table 1.

2.2. Chemical Properties

The chemical properties of aliphatic nitriles are determined by two reactive centers:

1) The electrophilic cyano group which can react with nucleophiles
2) The activated carbon adjacent to the nitrile group which is prone to base-catalyzed substitution reactions

Typical reactions involving the cyano group and the activated carbon adjacent to it are illustrated in Figures 1 and 2, respectively.

2.3. General Production Processes

Of the many synthetic pathways that can be envisaged for producing aliphatic nitriles, the following four are widely used:

Reaction of Nitrogen-Free Precursors (such as Alkanes, Olefins, Alcohols, Aldehydes, or Acids) with Ammonia. Gas phase reaction of *olefins with ammonia* in the presence of oxygen (ammoxidation) and oxidation catalysts (based on, e.g., vanadium or molybdenum) has attained the greatest industrial importance for the production of acrylonitrile from propene and methacrylonitrile from isobutene. This process is known as the *Sohio process* → Acrylonitrile.

$$H_2C{=}CH-CH_3 + NH_3 + 3/2\,O_2 \xrightarrow{\text{Catalyst}} H_2C{=}CH-CN + 3\,H_2O$$

Acetonitrile and hydrogen cyanide are formed as byproducts in typical quantities of 30 – 40 kg and 140 – 180 kg, respectively per 1000 kilograms of acrylonitrile [1]. Propane can also be used as feedstock (the first step being the in situ dehydrogenation to propene) as well as acrolein [2]. Similarly, the simplest aliphatic nitrile, hydrogen cyanide can be obtained from methane, ammonia, and oxygen (*Andrussow process,* see → Cyano Compounds; Inorganic, Chap. 1.2.1.).

The ammoxidation process can also be advantageously carried out with *aldehydes* as starting materials, when they are readily available. This is especially the case for butyraldehyde and isobutyraldehyde which yield butyronitrile and isobutyronitrile, respectively [3]. The ammonolysis of *alcohols* or *aldehydes* can also be conducted under dehydrogenation conditions [4]:

$$(H_3C)_2CH-CH_2OH + NH_3 \xrightarrow[290\,^\circ C]{Cu/SiO_2} (H_3C)_2CHCN + H_2O + 2\,H_2$$

Acids when reacted with ammonia over a dehydration catalyst such as Al_2O_3 at typical temperatures above 360 °C give nitriles without isolation of the intermediary amides [5].

Figure 1. Typical reactions involving the cyano group

Figure 2. Typical reactions involving the activated carbon atom adjacent to the cyano group

$$(H_3C)_3CCOOH + NH_3 \xrightarrow[380\,^\circ C]{Al_2O_3} (H_3C)_3CCN + 2\,H_2O$$

In addition to ammonia other nitrogen-containing reagents can be used, for example, hydroxylamine which easily yields nitriles upon reaction with aldehydes.

$$R-CHO + NH_2OH \xrightarrow{-H_2O} [R-CH=N-OH] \xrightarrow{-H_2O} R-CN$$

A multitude of dehydration agents is available.

Other nitrogen-containing reagents such as sulfonamides [6], hydroxylamine-*O*-sulfonic acid [7] and chlorosulfonylisocyanate [8] have also been investigated. However, none of those methods have gained industrial importance.

Formation of the Cyano Moiety from Nitrogen-Containing Precursors such as Amines, Amides, or Formamides. If an amine

is employed as starting material, it is usually produced in situ from the corresponding alcohol and ammonia, the dehydrogenation step is then performed catalytically [4]. An electrochemical dehydrogenation with a nickel hydroxide anode has also been investigated [9].

$$R-CH_2-NH_2 \xrightarrow[KOH,\ H_2O]{Ni(OH)_2/Anode,} R-CN + 2H_2$$

Dehydration of *amides* with agents such as aluminum chloride or thionyl chloride is a widely applicable method, although not competitive in most cases. The direct catalytic conversion of acids with ammonia is preferred.

Formamides are also valuable precursors [10]:

$$HCONHC(CH_3)_3 \xrightarrow[t > 250\,°C]{\text{Acetic anhydride}} (H_3C)_3CCN + H_2O$$

Reaction of Hydrogen Cyanide or Cyanide Ions with Double Bonds, Carbonyl Compounds, Hydrogen or Halogens. A typical industrial example of the hydrogen cyanide addition to *double bonds* is the direct hydrocyanation of butadiene to adiponitrile [11].

Reaction with aldehydes and ketones yields the corresponding cyanohydrins.

The reaction is usually carried out at 10–15 °C and a pH of 6.5–7.5. The cyanohydrin is continuously removed from the reaction mixture to shift the equilibrium toward cyanohydrin formation, which is usually stabilized with mineral acids or directly chemically converted to a more stable form [12].

A displacement reaction of hydrogen with a halogen cyanide, which has gained great industrial importance, is the synthesis of malononitrile from acetonitrile and cyanogen chloride above 700 °C (→ Malonic Acid and Derivatives):

$$H_3C-CN + ClCN \longrightarrow NC-CH_2-CN + HCl$$

The order of halogen reactivity towards cyanide displacement is Cl < Br < I, fluoride being essentially inert. Examples are the production of:

4-Chlorobutyronitrile from 1-bromo-3-chloropropane [13]

Adiponitrile via prior chlorination of butadiene [14]

Cyanoacetates from chloroacetic acid (→ Malonic Acid and Derivatives, Chap. 4.)

Another important reaction is the synthesis of acyl cyanides in the presence of copper(I) cyanide [15]:

$$H_3C-\overset{O}{\overset{\|}{C}}-Cl + NaCN \xrightarrow{CuCN} H_3C-\overset{O}{\overset{\|}{C}}-CN + NaCl$$

In addition to the readily available hydrogen cyanide or cyanide salts (e.g., sodium cyanide) other cyanation agents such as tetraalkylammonium cyanides [16] or trimethylsilylcyanide [17] have been investigated.

Reaction of the Activated Carbon in Nitrile-Containing Precursors. In addition to the examples highlighted in Figure 2 the electrohydrodimerization of acrylonitrile to adiponitrile, known as "EHD process" is also significant [18]:

$$2H_2C=CH-CN \xrightarrow[-2OH]{2e,\ H_2O} NC-(CH_2)_4-CN$$

2.4. Selected Aliphatic Nitriles

2.4.1. Saturated Mono- and Dinitriles

Acetonitrile [*75-05-8*], methylcyanide, cyanomethane, ethanenitrile, CH_3CN, is a colorless liquid miscible with water, ethanol and many organic solvents but immiscible with many saturated hydrocarbons (e.g., petroleum fractions). The physical properties are listed in Table 1. Characteristics of acetonitrile are its high dipole moment (3.84 D) and dielectric constant (38.8 at 20 °C).

Production. Acetonitrile and hydrogen cyanide are the principal byproducts from the ammoxidation of propylene to acrylonitrile (Sohio process). Some acrylonitrile producers recover and purify acetonitrile, but most companies burn the byproducts as plant fuel.

Economic Aspects. In 1986 the comsumption of acetonitrile amounted to ca. 13 000 t in the United States, Western Europe, and Japan [19]. Along with *N*-methylpyrrolidone and *N,N*-dimethylformamide, acetonitrile represents one of the major solvents for extraction of butadiene from crude C_4 streams. Acetonitrile is also a valuable reaction solvent, especially in the synthesis of antibiotics. Highly purified acetonitrile finds application as a solvent in high-performance liquid chromatography.

The major use of acetonitrile in *organic synthesis* is in the production of malononitrile through reaction with cyanogen chloride (→ Malonic Acid and Derivatives).

Other applications include the synthesis of trimethyl orthoacetate [$H_3C-C(OCH_3)_3$] and acetamidine hydrochloride [$H_3C-C(=NH)-NH_2 \cdot HCl$]. The former is used in the synthesis of 3-(2,2-dichlorovinyl)-2,2-dimethylcyclopropanecarboxylic acid (also known as DV-acid) which is a key precursor for pyrethroides [20]. The latter yields N-containing heterocycles such as 4-amino-5-cyano-2-methylpyrimidine used in the synthesis of thiamine [21].

Transport Classification: RID/ADR 3, no. 11B

Propionitrile [*107-12-0*], ethyl cyanide, CH_3CH_2CN, is a colorless liquid which is miscible with water, ethanol, dimethylformamide, and diethyl ether. The physical properties are listed in Table 1. Propionitrile is obtained either by hydrogenation of acrylonitrile [22] or by the gas-phase reaction of propanal or propanol with ammonia [4]. It is also obtained as a byproduct in the electrohydrodimerization of acrylonitrile to adiponitrile (EHD process) [18].

Hydrogenation of propionitrile yields *N*-propylamines [23]. It is also used as an organic intermediate, for example, in the synthesis of the pharmaceuticals flopropione (via Houben–Hoesch reaction) [24] and ketoprofen [25].

Transport Classification: RID/ADR 3, no. 11B

Butyronitrile [*109-74-0*], propyl cyanide, butanenitrile, $CH_3(CH_2)_2CN$, is a colorless liquid slightly miscible with water, miscible with ethanol and diethyl ether. The physical properties are listed in Table 1. Butyronitrile is usually obtained by the catalytic gase-phase reaction of butanol or butyraldehyde with ammonia [3,4]. Its major use is the manufacture of the poultry drug amprolium [26].

Transport Classification: RID/ADR 3, no. 11B

Isobutyronitrile [*78-82-0*], 2-methylpropanenitrile, isopropyl cyanide, 2-methylpropionitrile, $(CH_3)_2CHCN$, M_r 69.11, *mp* −71.5 °C, *bp* 117 °C (101.3 kPa), n_D^{20} 1.374, d_4^{20} 0.770, is a colorless liquid miscible with ethanol and diethyl ether, slightly miscible with water.

Isobutyronitrile is usually obtained by the catalytic gas-phase reaction of isobutyraldehyde or isobutanol with ammonia [3,4]. Its major use is the synthesis of the insecticide diazinon [27].

Transport Classification: RID/ADR 3, no. 11B

Succinonitrile [*110-61-2*], ethylene dicyanide, ethylene cyanide, dicyanoethane, butanedinitrile, $NCCH_2CH_2CN$, is a colorless, waxy solid slightly soluble in water and ethanol. The physical properties are listed in Table 1. Succinonitrile is obtained by addition of hydrogen cyanide to acrylonitrile [28]. Subsequent hydrogenation of succinonitrile yields 1,4-diaminobutane, which reacts with adipic acid to form the new polyamide 46. The polymer, developed by DSM (Netherlands), is marketed under the trade name Stanyl; the latter is reported to have excellent mechanical properties at high temperature [29].

Transport Classification: RID/ADR 6.1, no. 12C

2.4.2. Unsaturated Mono- and Dinitriles

Methacrylonitrile [*126-98-7*], 2-methyl-2-propenenitrile, $CH_2{=}C(CH_3)CN$, M_r 67.09, *mp* −35.8 °C, *bp* 90.3 °C, d_4^{20} 0.7998, n_D^{20} 1.4003, is a liquid which is miscible with ethanol, diethyl ether and acetone; it is immiscible with water.

Methacrylonitrile can be produced by ammoxidation of isobutene. Its copolymerization with methacrylic acid gives poly(methacrylimide), an engineering plastic commercialized under the trade name Rohacell by Röhm (Federal Republic of Germany) [30].

2-Methyleneglutaronitrile [*1572-52-7*], acrylonitrile dimer, 2,4-dicyano-1-butene, 2-methylenepentanedinitrile, NCC_2H_4C (=CH_2) CN, is a colorless liquid slightly miscible with water, ethanol, acetone and benzene, immiscible with hexane. The physical properties are listed in Table 1.

2-Methyleneglutaronitrile is obtained by dimerization of acrylonitrile in the presence of a metal halide and a tertiary amine [31]. Its hydrogenation yields 2-methylglutaronitrile, which in turn can be converted into 3-methylpyridine [32].

Tetracyanoethylene [*670-54-2*], ethenetetracarbonitrile, TCNE, $(NC)_2C=C(CN)_2$, M_r 128.09, *mp* 197 – 198 °C, *bp* 223 °C, n_D^{25} 1.560. The preferred synthetic preparation of TCNE involves the debromination of the KBr complex of dibromomalononitrile. Tetracyanoethylene is a reactive compound that undergoes a variety of reactions including addition, replacement and cyclization. The chemistry of TCNE is exhaustively reviewed in [33].

2.4.3. Substituted Nitriles

Chloroacetonitrile [*107-14-2*], chloromethanenitrile, chloromethyl cyanide, $ClCH_2CN$, M_r 75.50, *bp* 124 – 126 °C, d_4^{20} 1.1896, n_D^{20} 1.426, is a colorless liquid with pungent odor. It is miscible with hydrocarbons and ethanol; immiscible with water. Chloroacetonitrile can be selectively obtained by the photochemical chlorination of acetonitrile with chlorine in the presence of, for example, $SnCl_4$ [34]. Another method is based on the dehydration of chloroacetamide with, e.g., phosphorous pentoxide [35]. Chloroacetonitrile is used as an organic intermediate, e.g., in the synthesis of the cardiovascular drug guanethidine [36] and the insecticide fenoxycarb [37].

Transport Classification : RID/ADR 6.1, no. 11B

Trichloroacetonitrile [*545-06-2*], trichloroethanenitrile, trichloromethyl cyanide, CCl_3CN, M_r 144.40, *mp* – 42 °C, *bp* 85.7 °C (101.3 kPa), d_4^{25} 1.4403, n_D^{20} 1.4409, is a colorless liquid immiscible with water.

Trichloroacetonitrile can be obtained by dehydration of trichloroacetamide with phosphorous pentoxide [38] or by chlorination of acetonitrile with chlorine. Vapor phase chlorination in the presence of water [39] and photochemical chlorination in the presence of catalysts such as $HgCl_2$ or $AlCl_3$ have been reported [40]. Trichloroacetonitrile is an organic intermediate used, for example, in the synthesis of the fungicide etridiazole [41].

Transport Classification : RID/ADR 6.1, no. 11B

Glycolonitrile [*107-16-4*], hydroxyacetonitrile, formaldehyde cyanohydrin, $HOCH_2CN$, M_r 57.05, *bp* 183 °C (slight decomp.), d_4^{15} 1.104, n_D^{20} 1.4117. Anhydrous glycolonitrile is a colorless liquid which is miscible with water, ethanol and diethyl ether.

Glycolonitrile is obtained by reaction of aqueous formaldehyde and aqueous hydrogen cyanide, in the presence of catalysts such as sodium hydroxide [42]. It is usually handled as an aqueous solution. Anhydrous glycolonitrile tends to be unstable at high pH values and therefore must be stabilized by addition of small amounts of, e.g., phosphoric acid.

The bulk of the glycolonitrile produced is not isolated but further upgraded by reaction with amines. Depending on the molecular ratio, reaction with ammonia yields aminoacetonitrile, iminodiacetonitrile or nitrilotriacetonitrile. Reaction with ethylenediamine gives ethylenediaminetetraacetonitrile which, in turn, is hydrolyzed to ethylenediaminetetraacetic acid (EDTA), a well known sequestrant.

Aminoacetonitrile [*540-61-4*], glycinonitrile, cyanomethylamine, H_2NCH_2CN, M_r 56.07, *bp* 58 °C (20 kPa, partial decomp.).

Aminoacetonitrile is readily obtained as an aqueous solution by reacting an aqueous solution of glycolonitrile with liquid ammonia [43]. The solution is stabilized by lowering the pH with small amounts of sulfuric acid [44]. Aminoacetonitrile can also be isolated as the hydrochloride or sulfate.

Aminoacetonitrile is usually further hydrolyzed by sodium hydroxide to the sodium salt of glycine, which in turn is neutralized to glycine [45].

Lactonitrile [*78-97-7*], acetaldehyde cyanohydrin, 2-hydroxypropanenitrile, $H_3CCH(OH)CN$, M_r 71.08, *mp* −40 °C, *bp* 182–184 °C (decomp.), d_4^{20} 0.9877, n_D^{18} 1.4058, is a colorless or straw-colored liquid, which is miscible with water and ethanol; it is miscible with diethyl ether and carbon disulfide.

Lactonitrile is obtained by reaction of acetaldehyde with hydrogen cyanide in the presence of sodium hydroxide. It is mainly used in the synthesis of lactic acid and lactates through hydrolysis with sulfuric acid and esterification [46].

3-Aminopropionitrile, [*151-18-8*], 3-aminopropanenitrile, β-aminopropionitrile, $H_2N-CH_2-CH_2CN$, M_r 70.09, *bp* 185 °C (101.3 kPa), n_D^{20} 1.4396, is a colorless liquid which tends to slowly polymerize if stored in the presence of air. 3-Aminopropionitrile is prepared by the reaction of acrylonitrile with ammonia [47] and is mainly used as an intermediate in the manufacture of β-alanine and pantothenic acid [48].

3-Chloropropionitrile [*542-76-7*], 3-chloropropanenitrile, β-chloropropionitrile, $ClCH_2CH_2CN$, M_r 89.53, *mp* −51 °C, *bp* 175–176 °C (101.3 kPa), n_D^{20} 1.4360, d_4^{20} 1.1573, is a colorless liquid miscible with acetone, benzene, ethanol and diethyl ether. It can be obtained by hydrochlorination of acrylonitrile with hydrochloric acid [49] and is used as an organic intermediate in the synthesis of the H_2-receptor famotidine [50].

Transport Classification : RID/ADR 6.1, no. 11C

3-Hydroxypropionitrile [*109-78-4*], ethylene cyanohydrin, hydracrylonitrile, 3-hydroxypropanenitrile, $HOCH_2CH_2CN$, M_r 71.08, *mp* −46 °C, *bp* 228 °C (101.3 kPa, slight decomp.), d_4^{25} 1.0404, n_D^{20} 1.4240, is a straw-colored liquid, miscible with water, acetone, and ethanol; immiscible with benzene, carbon tetrachloride, and naphtha. 3-Hydroxypropionitrile is obtained by reacting ethylene oxide with hydrogen cyanide or from the hydration of acrylonitrile [51]. It was used as feedstock in the production of acrylic acid and acrylates.

4-Chlorobutyronitrile [*628-20-6*], 4-chlorobutanenitrile, $Cl(CH_2)_3CN$, M_r 103.55, *bp* 189–191 °C (101.3 kPa), d_4^{15} 1.0934, n_D^{20} 1.4413, is a liquid, miscible with ethanol and diethyl ether; it is immiscible with water.

4-Chlorobutyronitrile is readily obtained by reacting 1-bromo-3-chloropropane with sodium cyanide [13]. It is used in the synthesis of the pharmaceuticals buflomedil [52] and buspirone [53]. 4-Chlorobutyronitrile also yields cyclopropanecarbonitrile upon cyclization with base [54].

Diaminomaleonitrile [*1187-42-4*], HCN tetramer, "DAMN", 2,3-diamino-2-butenedinitrile, $NC(NH_2)C{=}C(NH_2)CN$, M_r 108.10, *mp* 183 °C (decomp.), n_D^{20} 1.5898, forms pale-brown needle shaped crystals. They are soluble in methanol, ethanol, and *N,N*-dimethylformamide; slightly soluble in water and dioxane; and insoluble in acetone, benzene, xylene, and carbon disulfide.

Diaminomaleonitrile is obtained by tetramerization of hydrocyanic acid in the presence of catalysts such as alkylaluminum compounds [55]. Nippon Soda runs a 200 t/a plant in Japan and intends to expand the production capacity in the future [56]. Diaminomaleonitrile is a versatile starting material for synthesizing nitrogen-containing heterocycles [57].

2.4.4. β-Iminonitriles

2-Amino-1-propene-1,1,3-tricarbonitrile [*868-54-2*], 2-amino-1,1,3-tricyanopropene, malononitrile dimer, $(NC)_2C{=}C(NH_2)CH_2CN$, M_r 132.13, *mp* 171 – 173 °C, is a light brownish powder, insoluble in water.

Malononitrile dimer is obtained from the base-catalyzed dimerization of malononitrile [58]. It has been investigated as a potential precursor for new dyes but it has no current industrial significance [59].

3-Amino-3-methylacrylonitrile [*1118-61-2*], β-iminobutyronitrile, β-aminocrotononitrile, diacetonitrile, 3-amino-2-butenenitrile, $NCCH{=}C(NH_2)CH_3$, M_r 82.11, *mp* (cis-form) 79 – 83 °C, *mp* (trans-form) 52 – 53 °C, d_4^{77} 0.9519, is a yellowish solid soluble in ethanol and diethyl ether; it is sparingly soluble in benzene and water.

3-Amino-3-methylacrylonitrile is obtained by the base-catalyzed dimerization of acetonitrile [60]. It is mainly used for the synthesis of pyrazolimines.

2.4.5. β-Ketonitriles

For details on *Cyanoacetic Acid* and its *Esters* see Malonic Acid and Derivatives, Chap. 3. Malonic Acid and Derivatives, Chap. 4.

Acetylacetonitrile [*2469-99-0*], β-ketobutyronitrile, 3-oxo-butanenitrile, $H_3CCOCCH_2CN$, M_r 83.09, *bp* 120 – 125 °C (101.3 kPa), can be obtained by hydrolysis of β-aminocrotononitrile [61]. A potential application is the synthesis of 3-amino-5-methylisoxazole, which is an intermediate for various drugs.

3,3-Dimethoxypropanenitrile [*57597-62-3*], cyanoacetaldehyde dimethyl acetal, 3,3-dimethoxy-propanenitrile, $(CH_3O)_2CHCH_2CN$, M_r 115.15, *bp* 195 °C, d_4^{20} 1.001, is a colorless to slightly yellow liquid.

3,3-Dimethoxypropanenitrile can be obtained from acrylonitrile by reaction with methanol in the presence of nitrite and platinum- or palladium-catalysts [62]. It is a valuable starting material for the synthesis of 4-aminopyrimidines such as cytosine.

2.5. Toxicology and Occupational Health

Occupational exposure to aliphatic nitriles mainly occurs by inhalation of vapors and/or by absorption through the skin. Pertinent toxicity and occupational health data relating to the most widely used aliphatic nitriles are summarized in Table 2.

The general toxicity of nitriles in humans includes gastric distress and vomiting, bronchial irritation, respiratory distress, convulsions, and coma. Animal toxicity studies also show gastrointestinal tract, liver, and pancreas irritations.

Whereas the old literature ascribes almost all the actions of nitriles to the liberation of cyanide ions, more recent reports tend to confirm that both the cyanide group and the entire molecule are important for biologic actions. While many of the neural effects are probably due to the cyanide moiety, the irritating and necrotic effects on the skin, liver, and kidney may be associated with the nature of the alkyl group. Although most aliphatic nitriles have cyanide release in common, there are significant differences in the amounts and duration exposure necessary to cause poisoning and toxicity effects. Signs of toxicity following oral administration of aliphatic nitriles to rats have highlighted the fact, that saturated nitriles affect the central nervous system in the same way as potassium cyanide, whereas unsaturated nitriles cause cholinomimetic effects such as salivation, diarrhea, and vasodilatation. Thus, cyanide release from unsaturated nitriles seems to play a minimal role in causing toxicity. Nitriles have tentatively been divided into three groups, with respect to toxicity, namely:

1) Those extensively metabolized to cyanide ions such as malononitrile and α-cyanohydrins
2) Those moderately metabolized to cyanide ions such as propionitrile and butyronitrile
3) Those poorly metabolized to cyanide ions such as acetonitrile, tetramethylsuccinonitrile, aminonitriles and acrylonitrile.

Table 2. Toxicological data

Nitrile	LD_{50}, mg/kg (oral, rats)	Inhalation, rats	LD_{50}, mg/kg (skin, rabbit)	Skin/eye irritation (rabbit)	Recommended workplace exposure limits, mg/m^3/type of limit
Saturated nitriles					
Acetonitrile	3800	LC_{50}: 7551 ppm/8h	1250	mild/severe	34/TWA; 70/MAK
Propionitrile	230	LCLo: 500 ppm/4h	210	mild/moderate	14/TWA
Butyronitrile	50	LCLo: 1000 ppm/4h	500	mild/mild	22/TWA
Isobutyronitrile	102	LCLo: 1000 ppm/4h	310	mild/mild	22/TWA
Saturated dinitriles					
Malononitrile	14			mild/mild	8/TWA
Succinonitrile	450				20/TWA
Adiponitrile	300				18/TWA
Unsaturated nitriles					
Acrylonitrile	78	LCLo: 500 ppm/4h	250	mild/severe	5/TWA
Allyl cyanide	115	LCLo: 500 ppm/4h	LDLo: 1410 (rabbit)	mild/mild	
Substituted nitriles					
Chloracetonitrile	220	LCLo: 250 ppm/4h	71	mild/moderate	
Cyanhydrins					
Acetoncyanhydrin	17	LCLo: 63 ppm/4h	17		4/C ∗
Glycolonitrile	16	LCLo: 250 ppm/4h	5		5/C ∗
Lactonitrile	87	LCLo: 125 ppm/4h	20		
3-Hydroxypropionitrile	3200		5000	mild/mild	

∗ C = Ceiling concentration not to be exceeded during a 15 min. sampling period.

3. Aromatic and Araliphatic Nitriles

Aromatic nitriles can be represented by the general formula Ar−C ≡ N. Further cyano groups or other substituents can be bonded to the aromatic nucleus. In *araliphatic* nitriles the aromatic nucleus is separated from the CN group by a $(CH_2)_n$ group, which can itself bear other substituents. Like the aliphatic nitriles the aromatic and araliphatic nitriles are important intermediates for organic synthesis.

3.1. Properties

Physical Properties. Aromatic and araliphatic nitriles are liquids or crystalline solids, mostly sparingly soluble in water (some heteroaromatic cyano-compounds have a higher water solubility) with sometimes considerable thermal stability. Benzonitrile and a range of substituted benzonitriles have a characteristic odor resembling bitter almonds. Some substituted benzonitriles sublime readily.

Chemical Properties. Reactions involving the cyano group are similar to the corresponding reactions of aliphatic nitriles (see Section 2.2). Ortho-substituents generally lower the reactivity of the cyano group. Functional groups attached to the aromatic ring normally react in the expected fashion. The bonds of halogens ortho and para to nitrile groups are weakened, i.e., these groups are prone to nucleophilic ipso-substitution. Ring-closure reactions involving the cyano-group are often possible. The nitrile group is a meta-directing substituent. The straight form of the cyano group allows even a hexacyano substitution at the benzene ring, in this case all six cyano groups being coplanar with the ring.

3.2. General Production Methods

Araliphatic nitriles can be produced by the methods similar to those described for aliphatic nitriles (see Section 2.3). The most important *cyanoaromatics*, e.g., benzonitrile, 2- and 4-chlorobenzonitrile, phthalonitrile, isophthalo- and terephthalonitrile, toluonitriles, and cyanopyridines are produced industrially by ammoxidation of the corresponding methylaromatics. Some newer special syntheses for aromatic nitriles also exist. The most important synthetic routes are shown schematically in Figure 3.

Figure 3. Synthetic routes to aromatic nitriles

Method 1 represents the ammoxidation, by which mono- and dinitriles are obtained [72]. For this reaction mixtures of aromatics (e.g., xylenes) can be also used, in this case nitrile mixtures are formed [73]. Liquid-phase ammoxidations in the presence of manganese (II) bromide are also known [74].

The acid-catalyzed treatment of aromatic carboxylic acids or their esters with ammonia, (method 3) at elevated temperatures in the gas phase, leads to the corresponding nitriles, often with good yields [75].

Elimination of water from aromatic aldoximes (method 4 a) is also performed with high yield. Many variants of this reaction can be found in the literature [76]. The dehydration of aromatic carboxamides is carried out similarly to that of aliphatic amides [77].

Reaction 5 (trichloromethylaromatics with ammonia or ammonium chloride) is catalyzed by iron (III) chloride [78].

The Houben – Fischer method (method 6) known for a long time, uses trichloroacetonitrile (see page 6) and thus leads to the unavoidable production of trichloromethane. In reaction 7 the pK value of the aromatic carboxylic acid should be higher than that of the acid from which the nitrile R – CN was formed. The conversion requires a temperature of 200 – 300 °C (pressure vessel) and frequently gives the nitrile in good yield. Acetonitrile, for example, is a suitable starting nitrile [79]. In place of the carboxylic acids, their alkali salts or esters can be used in some cases [80].

Formylation of an aromatic amine, subsequent thermal dehydration of the formanilide (reaction 11), and reaction via the isonitrile yields nitriles (analogous to the corresponding conversion of aliphatic amines) [81].

Some ether-substituted aromatics (e.g., anisole) react with cyanogen bromide in the presence of catalysts to form nitriles [82]:

Further special syntheses of aromatic nitriles include reactions of aromatic carboxylic acids with urea and amidosulfonic acid at 200 – 400 °C [12] or with chlorosulfonyl isocyanate and subsequent cleavage of the adduct with triethylamine [84].

3.3. Selected Araliphatic and Aromatic Nitriles

3.3.1. Araliphatic Nitriles

Phenylacetonitrile [*140-29-4*], α-cyanomethylbenzene, benzyl cyanide, M_r 117.14, *mp* − 26 °C, *bp* 233.5 °C, d_4^{20} 1.0157, n_D^{17} 1.5243, flash point 102 °C, is a colorless, oily, toxic liquid.

Phenylacetonitrile is produced by the reaction of benzyl chloride with alkali cyanide in alcohol or aqueous solution under phase trans-

fer catalysis with *N,N*-dialkylbenzylammonium chloride [85].

Phenylacetonitrile is used as an intermediate in the production of synthetic penicillins or barbiturates, in the synthesis of optical bleaches for fibers, in the production of insecticides, and for perfumes and flavors (via phenylacetic acid to "honey-type" ester compounds).

Labeling and transport: RID/ADR 6.1, no. 12C

1,2-Phenylenediacetonitrile [*613-73-0*], 1,2-bis-(cyanomethyl)benzene, M_r 156.18; *mp* 59 – 60 °C; forms colorless crystals.

The nitrile is used as an intermediate for the synthesis of optical brighteners and is produced by the reaction of 1,2-bis(chloromethyl)benzene with sodium cyanide in aqueous suspension under phase transfer catalysis [86].

Phenylglyoxylonitrile [*613-90-1*], benzoyl cyanide, M_r 131.13, *mp* 34 °C, *bp* 206 – 208 °C (101.3 kPa), *bp* 96 °C (2 kPa), *bp* 82 °C (1.2 kPa), n_D^{26} 1.5303, can be used for selective reactions at the carbonyl and cyano groups. It is produced from the reaction of benzoyl chloride or benzoic anhydride with sodium cyanide (or hydrogen cyanide in the presence of alkali cyanide) in practically quantitative yield with copper (I) cyanide as catalyst [87]. Benzoyl cyanide is used as an intermediate in the synthesis of plant protection agents.

Labeling and transport: RID/ADR 6.1, no. 24B

d,l-Mandelonitrile [*532-28-5*], benzaldehyde cyanohydrin, α-cyano-α-hydroxymethylbenzene, $C_6H_5-CH(OH)-CN$, M_r 133.15, *mp* – 10 °C, d_4^{20} 1.1165 – 1.120, is miscible with ethanol and diethyl ether, immiscible with water.

Mandelonitrile occurs naturally as the β-glycoside of gentiobiose (amygdalin). It decomposes on heating into benzaldehyde and hydrogen cyanide. It is produced from benzaldehyde and alkali cyanide in the presence of mineral acid [88]. Mandelonitrile is used as an intermediate in the production of mandelic acid (→ Hydroxycarboxylic Acids, Aromatic, Chap. 4.4.).

Benzothiazolyl-2-acetonitrile [*56278-50-3*], 2-cyanomethylbenzothiazole, M_r 174.21, *mp* 102 °C, forms colorless crystals.

This nitrile is produced by the reaction of 1-amino-2-mercaptobenzene (*o*-aminothiophenol) with the monoiminoether hydrochloride of malononitrile [89] and is used as a condensation component for methine dyes (→ Methine Dyes and Pigments, Chap. 7.3.3.).

3.3.2. Aromatic Nitriles

3.3.2.1. Cyanobenzenes

2-Chlorobenzonitrile [*873-32-5*], 2-chloro-1-cyanobenzene, M_r 137.57, *mp* 44.8 °C, *bp* (101.3 kPa) 232 °C, *bp* (1.6 kPa) 111.5 °C, forms colorless crystals that readily sublime. The crystals are readily soluble in organic solvents, only sparingly soluble in water, and steam volatile.

2-Chlorobenzonitrile is produced industrially by ammoxidation of 2-chlorotoluene [90]. It is used as an intermediate in the production of 2-amino-5-nitrobenzonitrile, which in turn is used for the synthesis of azo dyes (see below).

Labeling and transport: RID/ADR 6.1, no. 12C

4-Chlorobenzonitrile [*623-03-0*], 4-chloro-1-cyanobenzene, $Cl-C_6H_4-CN$, M_r 137.6, *mp* 97 °C, forms colorless crystals that can be sublimed. The compound is steam volatile, readily soluble in organic solvents, and only sparingly soluble in water. 4-Chlorobenzonitrile is produced industrially by the ammoxidation of 4-chlorotoluene [91]. It is used in the synthesis of a red pigment for plastics [92].

2,6-Dichlorobenzonitrile [*1194-65-6*], 1-cyano-2,6-dichlorobenzene, M_r 172.02, *mp* 144.5 – 146.5 °C, is a colorless, crystalline substance. Its solubility in water is 10 ppm at 25 °C. 2,6-Dichlorobenzonitrile is produced industrially by the ammoxidation of 2,6-dichlorotoluene [93]. In addition the nitrile is obtained by oxidation or side-chain-chlorination of 2,6-dichlorotoluene via 2,6-dichlorobenzoic acid and 2,6-dichlorobenzaldehyde, respectively. 2,6-Dichlorobenzonitrile shows herbicidal activity (Casoron, Duphar) and is used in fruit and vine cultivation. It is also used as

an intermediate in the production of 2,6-difluorobenzonitrile and of 2,6-dichlorothiobenzamide (Prefix, Shell) which shows herbicidal activity.

2,6-Difluorobenzonitrile [*1897-52-5*], 1-cyano-2,6-difluorobenzene, M_r 172.02, *mp* 29 – 30 °C, forms colorless crystals. The nitrile can be produced by treatment of 2,6-dichlorobenzonitrile with potassium fluoride in sulfolane [23] and is used as an intermediate in the synthesis of insecticides (e.g., Dimilin, Shell).

2-Chloro-4-nitrobenzonitrile [*28163-00-0*], 2-chloro-1-cyano-4-nitrobenzene, M_r 182.57, *mp* 81 °C, is produced by the reaction of the diazonium salt derived from 2-chloro-4-nitroaniline with copper cyanide (Sandmeyer reaction) [95]. 4-Amino-2-chlorobenzonitrile can be obtained from 2-chloro-4-nitrobenzonitrile by reduction of the nitro group with iron (Béchamp method): it is used as an intermediate for the production of azo dyes.

4-Chloro-2-nitrobenzonitrile [*34662-32-3*], 1-chloro-4-cyano-3-nitrobenzene, M_r 182.57, *mp* 100 – 101 °C, is obtained by the Sandmeyer reaction of 4-chloro-2-nitrobenzene diazonium salt with copper cyanide [95]. Reduction of the nitro group with iron yields 2-amino-4-chlorobenzonitrile: the latter is an intermediate for the production of azo dyes.

2-Chloro-5-nitrobenzonitrile [*16588-02-6*], 1-chloro-2-cyano-4-nitrobenzene, M_r 182.57, *mp* 108 – 109 °C, forms yellow needle-shaped crystals. The chlorine atom ortho to the nitrile group is prone to a range of nucleophilic substitution reactions, of which that with ammonia has achieved industrial importance [96]. The nitrile is produced by nitration of 2-chlorobenzonitrile (see above) at 0 °C [97].

2-Amino-5-nitrobenzonitrile [*17420-30-3*], 2-cyano-4-nitroaniline, M_r 163.13, *mp* 210 °C, is readily soluble in acetone, chloroform, and benzene; itis sparingly soluble in water and ethanol. As already mentioned, the reaction of 2-chloro-5-nitrobenzonitrile (see above) with ammonia gives 2-amino-5-nitrobenzonitrile [98], an intermediate for azo dyes. A newer synthetic route starts from 6-nitroisatoic anhydride [2H-3,1-benzoxazine-6-nitro-2,4 (1H)-dione]: the latter is converted into 2-amino-5-nitrobenzonitrile by reaction with ammonia, subsequent treatment with phosgene in dimethylformamide or *N*-methylpyrrolidone, followed by hydrolysis of the formamidine [77].

4-Hydroxybenzonitrile [*767-00-0*], 4-cyanophenol, 1-cyano-4-hydroxybenzene, M_r 119.2, forms colorless crystals of *mp* 113 °C. 4-Hydroxybenzonitrile is produced by reaction of 4-bromophenol with copper (I) cyanide [99], by ammoxidation of *p*-cresol [100], by reaction of 4-chlorobenzonitrile with sodium methoxide [101], or by the catalyzed gas phase reaction of ethyl 4-hydroxybenzoate with ammonia [75]. The nitrile is used for the production of the herbicides 3,5-dibromo- and 3,5-diiodo-4-hydroxybenzonitrile (Bromoxynil, Ioxynil, May & Baker).

3.3.2.2. Cyanonaphthalenes (Naphthalene Carboxylic Acid Nitriles)

In principle cyanonaphthalenes can be produced by the general methods given in Section 3.2. Additional production methods involving ring-closure condensation reactions are described under 1,4-dicyanonaphthalene. The industrial importance of cyanonaphthalenes is low.

1-Cyanonaphthalene [*86-53-3*], α-naphthonitrile, 1-naphthoic acid nitrile, M_r 153.17, *mp* 35.5 – 36 °C, *bp* 296 – 299 °C, forms colorless crystals that are readily soluble in ethanol. It is used in organic synthesis.

2-Cyanonaphthalene [*613-46-7*], β-naphthonitrile, 2-naphthoic acid nitrile, M_r 153.17, *mp* 66 °C, *bp* 303 °C, forms colorless crystals that are readily soluble in ethanol. It is

used in organic synthesis and suitable as a reaction medium for obtaining propylene from ethylene and 2-butene by olefin metathesis [102].

1,4-Dicyanonaphthalene [*3029-30-9*], naphthalene-1,4-dicarboxylic acid dinitrile, M_r 178.18, *mp* 208 °C, crystallizes in long, colorless needles. 1,4-Dicyanonaphthalene is produced by condensation of 1,2-phenylenediacetonitrile (see page 11) with glyoxal or its bisaldimines [103]. It is used as an intermediate for the synthesis of optical brighteners and dyes from naphtholactams.

2,6-Dicyanonaphthalene [*31656-49-2*], naphthalene-2,6-dicarboxylic acid dinitrile, M_r 178.18, *mp* 294 – 297 °C, can be obtained by ammoxidation of 2,6-dimethylnaphthalene on sodium vanadate bronzes doped with Fe_2O_3 [104]. It is used for the production of 2,6-bis(aminomethyl)naphthalene, an intermediate for dyes.

6-Cyano-β-naphthol [*52927-22-7*], 6-cyano-2-hydroxynaphthalene, 6-hydroxy-2-naphthoic acid nitrile, M_r 169.17, *mp* 166 – 167 °C. This nitrile is used as an intermediate for the production of liquid crystals [105] and monoamino-oxidase-inhibiting naphthalene-2-oxyalkylamines, which are used as antidepressive agents [106].

3.4. Toxicology

Mandelonitrile is rather toxic with an LD_{50} value (rat, oral) of 116 mg/kg [107]. This high toxicity may be due to the equilibrium of the cyanohydrin with benzaldehyde and hydrogen cyanide.

Phenylacetonitrile has an oral LD_{50} value (rat) of 270 mg/kg [108].

Benzonitriles with Methyl Substituents. The various methyl-substituted derivatives (2-, 3-, and 4-methylbenzonitrile and 2,3-, 2,4-, and 2,5-dimethylbenzonitrile) are less toxic than benzonitrile itself (→ Benzoic Acid, Chap. 9.). Their LD_{50} values (rat, oral) are in the range 3000 – 4500 mg/kg [109]. The monomethylbenzonitriles are reported to be metabolized by oxidation of the methyl group [109]. Mono- and dimethylbenzonitriles generally show a stronger irritating effect on the skin and mucous membrane than benzonitrile [109].

Miscellaneous Substituted Benzonitriles. The oral LD_{50} values of some substituted benzonitriles are as follows:

2-Chlorobenzonitrile	435 mg/kg [109]
4-Chlorobenzonitrile	887 mg/kg [107]
2,6-Dichlorobenzonitrile	2710 mg/kg [107]
2-Chloro-5-nitrobenzonitrile	3200 mg/kg [109]
4-Nitrobenzonitrile	30 mg/kg [109]

The LD_{50} values (rat, oral) for nitriles which are used as herbicides are as follows [110]:

3,5-Diiodo-4-hydroxybenzonitrile	305 mg/kg
3,5-Dibromo-4-octanoyloxybenzonitrile	420 mg/kg
Trichlorophenylacetonitrile	1050 mg/kg
Diphenylacetonitrile	200 mg/kg

1. Introduction

Nitrilotriacetic acid [*139-13-9*], NTA, *N,N*-bis(carboxymethyl)glycine, along with ethylenediaminetetraacetic acid (EDTA, → Ethylenediaminetetraacetic Acid and Related Chelating Agents) is one of the most important aminopolycarboxylate chelating agents.

Its synthesis from ammonia and chloroacetic acid was accomplished by Heintz as early as 1861 [1]. Industrial production first took place in 1936 in Ludwigshafen. Since that time, NTA has become an established chelating agent and is used in many industries where multivalent metal ions, chiefly alkaline-earth ions, must be "masked" in order to modify their properties or prevent typical reactions such as the formation of insoluble precipitates.

2. Properties

Physical Properties. Nitrilotriacetic acid, $C_6H_9NO_6$, M_r 191.14, is a tribasic acid, crystallizing from water as colorless needles. The most important physical data are as follows [2]:

mp (decomp.)	242 °C
Solubility in water, g/100 g	
5 °C	0.13
22.5 °C	0.13
80 °C	0.95
100 °C	3.3
Dissociation constants [3] (25 °C, ionic strength = 0.1 mol/L)	
pK_1	1.80
pK_2	2.48
pK_3	9.65

The pH of a saturated solution (ca. 0.13 g NTA per 100 g of solution at room temperature) is ca. 2.3. The alkali-metal salts are the most soluble NTA salts. For example, ca. 640 g of trisodium nitrilotriacetate [*5064-31-3*] dissolve in 1 L of water.

Chemical Properties. The most important property of NTA is its ability to form watersoluble chelates with multivalent metal ions. Not only the carboxyl groups but also the tertiary nitrogen atom function as ligands. Unoccupied coordination sites of the metal ion can be saturated by water molecules. Although the chelates of NTA with metal ions are often represented as octahedral (coordination number 6) for the sake of simplicity, recent structural studies (chiefly by X-ray methods) have shown that higher coordination numbers are also possible for some metal ions. For example, Ca^{2+} in the chelate $CaNTA^-$ has a coordination number of 7 [4].

As a rule, complexes are 1 : 1, i.e., 1 mol of metal ions reacts with 1 mol of NTA. If NTA is present in excess, 1 : 2 complexes with 1 mol of metal ions complexed by 2 mol of NTA are formed.

The stability of the metal complex is described by stability constants (K_1 for 1 : 1 complexes, K_2 for 1 : 2 complexes; see Table 1).

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a17_377

Further, because of the polarization of the H−O bond in the chelate, the 1 : 1 complexes behave as weak acids and dissociate. This effect is described by the dissociation constant K_d:

$$K_1 = \frac{[\mathrm{MNTA}]}{[\mathrm{M}]\,[\mathrm{NTA}]}$$

$$K_2 = \frac{[\mathrm{MNTA_2}]}{[\mathrm{M}]\,[\mathrm{NTA}]^2}$$

$$K_d = \frac{[\mathrm{MNTAOH}]\,[\mathrm{H^+}]}{[\mathrm{MNTA}]}$$

where M is a multivalent metal ion, NTA represents the anion $N(CH_2COO^-)_3$, and the charges have been omitted for simplicity except for H^+.

Table 1. Stability constants for NTA chelates∗ [3]

Metal ion	$\log K_1$	$\log K_2$	pK_d
Al^{3+}	11.4		5.09
Ca^{2+}	6.39	8.76	
Cd^{2+}	9.78	14.39	11.25
Co^{2+}	10.38	14.33	10.80
Cu^{2+}	12.94	17.42	9.14
Fe^{2+}	8.33	12.80	10.60
Fe^{3+}	15.90	24.30	4.1/7.8∗∗
Hg^{2+}	14.60		
Mg^{2+}	5.47		
Mn^{2+}	7.46	10.94	
Ni^{2+}	11.50	16.32	10.86
Pb^{2+}	11.34		
Zn^{2+}	10.66	14.24	10.06

∗ Ionic strength (25 °C) = 0.1 mol/L.
∗∗ Behaves as a dibasic acid.

Complexing of metal ions with NTA competes with other secondary reactions. For example, metal ions react with anions such as carbonate, sulfide, sulfate, or oxalate to form sparingly soluble precipitates, and hydrogen ions compete with metal ions for sites on the NTA trianion. This means that several equilibria must be taken into consideration in the analysis of NTA systems.

Nitrilotriacetate chelates are stable over relatively wide pH ranges that depend on the concentration of the chelate and the excess of the complexing agent: Ca^{2+}, pH 9 – 12; Mg^{2+}, pH 7 – 10; Cu^{2+}, pH 3 – 12; Fe^{3+}, pH 1.5 – 3. Assuming a stoichiometric ratio for 1 : 1 complexing, in the optimal pH range 1 g of Na_3NTA binds 156 mg of Ca^{2+}, 94 mg of Mg^{2+}, 247 mg of Cu^{2+}, or 217 mg of Fe^{3+}.

3. Production

The original synthesis of NTA from ammonia and chloroacetic acid has only historical significance [1]. The oxidation of triethanolamine is likewise of no industrial importance [5]. The one-stage alkaline and two-stage acid processes in use are based on the cyanomethylation of ammonia (or ammonium sulfate) with formaldehyde and sodium cyanide (or hydrogen cyanide).

Alkaline Process. The alkaline process was long the established method for NTA production. Trisodium nitriloacetate is synthesized as follows:

$$NH_3 + 3\,HCHO + 3\,NaCN \rightarrow N(CH_2CN)_3 + 3\,NaOH$$

$$N(CH_2CN)_3 + 3\,NaOH + 3\,H_2O \rightarrow N(CH_2COONa)_3 + 3\,NH_3$$

The reaction can be carried out batchwise or continuously, but the continuous process is more economical.

In a typical process, aqueous NaCN solution is fed into a cascade reactor system along with formaldehyde solution [6]. Ammonia is liberated during the synthesis and need not be supplied. The reaction takes place at 80 – 100 °C. Because of the high pH (ca. 14), triscyanomethylamine $N(CH_2CN)_3$ [*7327-60-8*] is hydrolyzed in situ to Na_3NTA. This process generates three times as much ammonia as it consumes and the ammonia concentration must be limited to suppress the production of substances with low degrees of carboxymethylation (glycine, iminodiacetic acid). This is largely achieved by continuously distilling off the ammonia with steam or air throughout the process. However, formation of byproducts (chiefly glycolic acid, hexamethylenetetramine, and the above-mentioned amino acids) cannot be completely prevented.

The resulting solution is sold directly as a 40-wt % solution, or used in the production of $Na_3NTA \cdot H_2O$ in powder form, or acidified to pH 1 – 2 to yield the acid (H_3NTA).

Acid Process [7]. The significant yield of byproducts in the alkaline process has led in recent years to the construction of plants based on the acid process, which features much lower byproduct levels. The acid process is associated

with stringent safety requirements due to the use of hydrogen cyanide; corrosion can also be a problem.

In the first stage, ammonia is reacted with formaldehyde to give hexamethylenetetramine, which is then reacted with hydrogen cyanide in sulfuric acid solution to yield triscyanomethylamine. The solid triscyanomethylamine is sparingly soluble in the acidic solution and is filtered off, washed, and saponified with NaOH to give Na_3NTA. The resulting solution has a far lower byproduct content than the solution from the alkaline method. It is also sold as 40 % product or used in the production of $Na_3NTA \cdot H_2O$ or H_3NTA (see above).

Trade Names. The following trade names apply to the most important NTA products: Dissolvine A grades (Akzo), Hampshire NTA grades (W. R. Grace), Masquol NTA grades (Protex), Nervanaid NTA grades (ABM Chemicals), Rexene NTA grades (Rexolin Chemicals), Trilon A grades (BASF), and Versene NTA grades (Dow).

4. Analysis

A number of methods are suitable for the quantitative determination of NTA and its salts. One widely used technique is potentiometric titration with iron(III) chloride under acidic conditions [8, 13]. Ion-pair chromatography [9], GC analysis [10], and polarographic determinations [11] can also be employed in the trace range.

5. Uses

The uses of NTA and its salts are based on their complexing properties for metal ions [12, 13]. It is employed in many areas to eliminate the interfering effects of metal ions by complexing, to dissolve precipitates, to modify the redox potentials of metal ions, or to prepare metal-ion buffers. The most important application areas are described below.

Water Softening. Nitrilotriacetic acid softens water by complexing Ca^{2+} and Mg^{2+} ions; complexation occurs in the neutral to basic range. The softening of water with hardnesses of 1 °d, 1 °f, 1 °e, and 1 mmol Ca^{2+}/L requires the following amounts of chelating agent: 34, 19, 27, and 191 mg NTA, or 46, 26, 36, and 257 mg Na_3NTA, respectively. [1 °d (German hardness) corresponds to 0.01 g CaO/L water, 1 °e (English hardness) to 0.01 g $CaCO_3$/0.7 L water, and 1 °f (French hardness) to 0.01 g $CaCO_3$/L water.]

Water softening with NTA is used in the paper and textile industries, soap manufacture, cosmetics and toiletries, the production of detergents and cleansers, the treatment of boiler feedwater, and in many chemical process industries (e.g., photographic materials and electroplating industries).

Phosphate Replacement in Detergents. Na_3NTA can be used as a substitute for pentasodium triphosphate in the formulation of low phosphate detergents or, with zeolite and sometimes polycarboxylates, in phosphate-free detergents (→ Laundry Detergents, Chap. 3.2.4.). Substitution of phosphates can help reduce the eutrophication of surface waters.

In comparison with pentasodium triphosphate, Na_3NTA has the advantage of resisting hydrolysis, so that it remains fully effective after spray drying of the detergent slurry and also during washing. The equivalence ratio of Na_3NTA to pentasodium triphosphate is about 0.6 to 1 and there is no detrimental effect on primary and secondary detergency (anti-redeposition).

Replacement of Tetrapotassium Diphosphate in Cleansers. The equivalence ratio of Na_3NTA to tetrapotassium diphosphate is favorable (ca. 1 : 3) and only low concentrations of Na_3NTA are needed in cleansers. This often makes the use of hydrotropes or solubilizers superfluous. Synergetic builder effects occur with partial substitution of the phosphate.

Masking of Heavy-Metal Ions. Although inferior to EDTA in many applications, NTA is also frequently employed for masking heavy-metal ions because of its greater specific complexing power for interfering ions such as Fe^{3+}, Cu^{2+}, and Mn^{2+}. Examples of such applications are in soap manufacture, textile bleaching, the cleaning of hard surfaces, and in many areas of the chemical process industries.

Special applications include the separation of rare-earth elements, complexometric titrations, and the preparation of micronutrients for agriculture.

6. Economic Aspects

It is difficult to state figures for production capacity of NTA mainly because all existing plants can also be used for producing other aminopolycarboxylates. A worldwide capacity of ca. 100 000 t seems realistic however [15].

World consumption of Na_3NTA (as 100 % product) was ca. 40 000 t in 1985 and about 70 000 t in 1989 [15]. There continues to be excess production capacity, built when a rapid increase in demand was expected for the formulation of phosphate-free and low-phosphate detergents, chiefly in the United States. The expected increase has only taken place in Canada, where ca. 40 000 t of Na_3NTA were used in 1988. In Western Europe, consumption is ca. 20 000 t/a; NTA is only used in detergents in a few European countries (Switzerland, The Netherlands). Consumption in the United States has stagnated at 5000 – 7000 t/a for industrial and institutional applications [14].

Important manufacturers are Monsanto (USA), W. R. Grace (USA, UK), BASF (FRG), ABM Chemicals (UK), Akzo (Netherlands), Aminkemi (Sweden), SA Dabeer (Spain), and Protex (France).

It is hard to predict market development for the coming years. Sizable increases should be expected in Western Europe if a number of countries (especially the FRG) adopt the use of NTA in detergents.

7. Toxicology and Environmental Aspects

The results of extensive studies on the environmental behavior and toxicology of NTA have been summarized [16–18].

After adaptation of relevant microorganisms (i.e., production of necessary enzymes), NTA is readily biodegradable. It is completely degraded to inorganic end products (i.e., mineralized) without any measurable concentration of organic metabolites being produced. Environmental studies performed after the introduction of NTA-containing detergents in Switzerland, also confirm the good biodegradability: $> 98\,\%$ of the NTA is biodegraded in biological water treatment plants [19–21]. The half-life in the receiving water is < 1 d [22]; virtually no NTA could be detected in ground water after infiltrating a few meters [23, 24].

As a powerful complexing agent, NTA can form heavy-metal complexes under certain conditions. Whether such an effect occurs in the environment depends on the NTA concentration. Since NTA is rapidly biodegraded, remobilization of heavy metals from the activated sludge of water treatment plants is negligible in comparison with the normal heavy-metal levels in the effluent [22, 23]. The same applies to the remobilization of heavy metals from river sediments, where under realistic conditions no measurable changes in the heavy-metal concentrations can be expected.

The acute toxicity to aquatic organisms is slight. Data for more than 50 freshwater and marine species are known; LC_{50} values vary from ca. 100 to $> 10\,000$ mg/L. The numerical values depend highly on the hardness of the test medium. Numerous studies have also been performed on the chronic toxicity of NTA in microorganisms, macroinvertebrates, amphibians, and fish. No toxic effects are seen at NTA concentrations below 1 mg/L. In most organisms, perceptible toxic effects only occur at very much higher levels.

The acute toxicity in mammals is species dependent. For example, LD_{50} (oral) values of ca. 2000 mg/kg are found for the trisodium salt ($Na_3NTA \cdot H_2O$) in rodents; vomiting occurs in dogs and monkeys. After inhaling 5 mg of NTA dust per liter of respired air over 4 h, rats displayed no clinical symptoms. The irritant action of NTA on the skin, eyes, and respiratory tract is slight; indications of sensitization and allergies are not known. Nitrilotriacetic acid is not teratogenic either by itself or in combination with heavy metals such as cadmium and mercury. Numerous mutagenicity tests have not shown indications of genotoxicity.

Nitrilotriacetic acid is not metabolized by mammals; any absorbed NTA is excreted unaltered by the kidneys. Tissue concentrations are highest in the cells of the renal tubules and in the

ureters. Subchronic and chronic studies therefore show toxic lesions of the kidneys, which can be attributed to disorders of electrolyte and iron metabolism. High doses (e.g., 2000 mg per kilogram body weight per day) result in injury to the epithelial cells of kidneys, ureters, and bladder, and as a consequence to tumor formation. There is, however, a threshold concentration below which tumors cannot develop. The threshold concentration is much higher than the NOEL (no adverse effect level) of 14 mg per kilogram body weight per day.

1. Structure and Color

Nitro dyes are characterized by the fact that a nitro group is conjugated with an electron donating group via an aromatic system. In all industrially important dyes the nitro and donor groups are ortho to each other. A further donor group can also be present.

The donors are usually hydroxyl and amino groups. The hydroxynitro dyes used industrially always contain several nitro groups. In the aminonitro dyes the nitrogen can bear alkyl or aryl groups. In heterocyclic nitro dyes the amino nitrogen is part of a heterocyclic ring system which has been condensed with the aromatic ring bearing the nitro group.

There are also nitro dyes that contain a second color-producing system, e.g., azonitro dyes, anthraquinone nitro dyes, and quinophthalone nitro dyes.

The simple nitroaniline and nitrophenol derivatives are yellow dyes. Substitution of the amino nitrogen gives a bathochromic shift towards orange-yellow color shades.

The 2,5-, 2,4-, and 3,4-didonor-substituted nitrobenzene derivatives extend the range of color shades considerably (Table 1).

The 2,5-disubstituted compounds have the longest wavelength absorption, and the 2,4-disubstituted ones the shortest.

Table 1. Color – structure relationship among nitro dyes

Electron donors		Longest wavelength maxima (ethanol)		
D	D′	2,4-D,D′	3,4-D,D′	2,5-D,D′
NH_2	NH_2	389	408	471
NHR	NH_2			495 – 497 ∗
NH_2	NHR		431	490 – 492 ∗
NHR	NRR			506 – 536 ∗
OH	NH_2	394	394	446
NH_2	OH	394	370	454
OH	NHR	403	412	477
OH	OH	376	390	400

∗ R = methyl at low end of range; R = 2-hydroxyethyl at high end.

The color range of the didonor-substituted nitrobenzene derivatives extends from the greenish yellow of 2,4-diaminonitrobenzene [*5131-58-8*] (**3**) ($D = D' = NH_2$) to the blue-violet of N^2,N^5,N^5-tris(2-hydroxyethyl)-2,5-diaminonitrobenzene [*33229-34-4*] (**1**) ($D = NHCH_2CH_2OH$, $D' = N(CH_2CH_2OH)_2$). 2,5-Diaminonitrobenzene [*5307-14-2*] (**1**) ($D = D' = NH_2$) and 4-(2-hydroxyethylamino)-3-nitrophenol [*65235-31-6*] (**1**) ($D = NHCH_2CH_2OH$, $D' = OH$) are red dyes. Sub-

stituted nitrodiphenylamine derivatives give orange to magenta shades.

Nitroso dyes always contain a hydroxyl group as donor. They can be formulated as tautomers of the quinone oxime and are capable of forming metal complexes.

The iron complexes are green pigments.

2. History

The oldest nitro dye is picric acid [*88-89-1*], which was first obtained in 1771 by WOULFE by treating indigo with nitric acid. In 1843 LAURENT determined its structure and prepared it by nitrating phenol. MARTIUS nitrated α-naphthol in 1864 to give the dye Martius yellow. Naphthol Yellow S [*483-84-1*], the first acid hydroxynitro dye, was prepared by CARO in 1879. In 1898 aminonitrobenzene dyes were used for the first time as toners in hair dyeing. The first acid aminonitro dye, Amido Yellow E [*6373-74-6*], was obtained by SCHMIDLIN in 1911. In 1908, Lithol Fast Yellow GG [*2955-16-0*] was the first nitro dye to be used as a pigment. Nitrodiphenylamine disperse dyes achieved importance with the development of cellulose acetate fibers. Important contributions to their development were made by MEYER, HOPFF, and ELLIS in 1924. GMELIN and FISCHER prepared the first 2-nitrodiphenylamine-4-sulfonamides in 1936, and this work was continued by KOPP and GANGNEUX in 1941. Later it became apparent that these dyes were particularly suitable for lightfast dyeing of polyester fibers. More recently, nitro dyes have also been used for transfer printing on polyester woven fabrics and in modern reproduction processes (ink-jet printing, optical data recording, and thermal transfer printing).

1-Nitroso-2-naphthol was prepared by FUCHS in 1875; its iron complex is Pigment Green B. In 1883 HOFFMANN obtained the soluble iron complex Naphthol Green B [*6636-34-6*] from 1-nitroso-2-naphthol-6-sulfonic acid.

3. Uses

Acid nitro dyes were first used to dye wool. More recently they have, like the acid azonitro dyes, been used for dyeing polyamide fibers. Water-insoluble nitro dyes are used either as disperse dyes for polyester materials or as pigments, depending on their structure. Low molecular mass dyes are suitable for transfer printing on polyester materials [4]. Alkylaminonitro dyes with long-chain alkyl groups are suitable for dyeing fats and oils. Cationic nitro dyes, in particular nitroazo dyes, are occasionally used for dyeing polyacrylonitrile. Nitro dyes are also used in ink-jet printing [5] and optical data storage [6]. Apart from dyeing, nitro dyes are used as herbicides or fungicides, and picric acid and hexanitrodiphenylamine [*2844-92-0*] as explosives.

4. Hydroxynitro Dyes

Picric acid (**4**) was formerly used for dyeing wool, silk, and leather. It has been recommended for the colored electrophoretic coating of aluminum as a mixture with alkyd resins [7].

4 [*88-89-1*]

Martius Yellow, 2,4-dinitro-1-naphthol, protects woven woolen material against moths, but has now been replaced by colorless compounds. A sulfonic acid derivative, Naphthol Yellow S (**5**), is obtained by treating 1-naphthol-2,4,7-trisulfonic acid with nitric acid. It can be used to dye wool and silk yellow.

5 [*483-84-1*]

5. Aminonitro Dyes

Aminonitro dyes have low color strength. The molar extinction coefficient is 4000

$L\,mol^{-1} \cdot cm^{-1}$ for *N*-alkylaminonitro dyes and 6000 to 7000 $L\,mol^{-1} \cdot cm^{-1}$ for *N*-arylaminonitro dyes. Only on the introduction of an azo chromophore does the molar extinction coefficient rise to 14 000 $L\,mol^{-1} \cdot cm^{-1}$ [8]. Since some of these dyes have high lightfastness and low production costs, they are nevertheless still in use.

5.1. Alkylaminonitro Dyes

Aminonitro dyes with tert-alkyl groups on the amino nitrogen are suitable for dyeing polyester, triacetate, and acetate rayon materials [9].

6 [*28799-71-5*]

The dye **6** colors these fibers greenish yellow. Dyes of this type are also suitable for dyeing organic solvents, oils, fats, waxes, or resins. Dyes with longer alkyl groups, e.g., the compound **7**,

7

are used to color gasoline and mineral oils [10]. An example is C.I. Solvent Yellow 96 (Sudan Yellow G, BASF).

Hydroxyalkylaminonitro dyes that have been esterified with unsaturated carboxylic acids such as acrylic acid can be polymerized and used in polymer form for dyeing leather coatings [11]. A commercial product: Corial Yellow H3G (BASF).

Yellow pigments are obtained by condensation of nitroanilines with aqueous formaldehyde. Lithol Fast Yellow GG (**8**) is used to color paints [12].

8 [*2955-16-0*]

An acid dye **9**, with two alkylaminonitro dye groups, is obtained by treating 2 mol 2-nitrochlorobenzene-4-sulfonic acid with 1 mol 1,4-bis(aminomethyl)benzene [13].

9

Silicon-containing reactive dyes are derived from 2,4-dinitroaniline. The dye **10** is suitable for dyeing natural and synthetic fiber materials and glass fibers [14].

10

Cationic nitro dyes such as **11** are obtained by treatment of an aliphatic triamine with 2-nitrochlorobenzene [15]. The dye **11** colors polyacrylonitrile yellow.

11

Compounds that are quaternized at the central nitrogen atom are also recommended for dyeing polyacrylonitrile and acid-modified polyamide fibers [16].

Nitro dyes with two alkyl groups on the amino nitrogen, e.g., the 2-nitro-*N*,*N*-dimethylaniline-4-sulfonamides, are also suitable for dyeing synthetic fibers. The sulfonic acid-4-ethoxyanilide is known commercially as C.I. Disperse Yellow 86 [*67338-59-4*]. The alkylamides are recommended for transfer printing on woven polyesters [17].

5.2. Arylaminonitro Dyes

Among the arylaminonitro dyes, the disperse dyes and those with sulfonic acid groups are particularly important. Cationic dyes are also known within this class of compounds.

5.2.1. Arylaminonitro Disperse Dyes

The simplest member of this series of dyes is 2-nitrodiphenylamine [*119-75-5*]. It is produced from 2-nitrochlorobenzene and aniline in the presence of copper oxide and *N*-methylpyrrolidone as catalyst. Potassium carbonate is added to bind the hydrochloric acid formed [18]. The reaction is accelerated by the addition of a quaternary tetraalkyl- or benzyltrialkylammonium salt. The corresponding phosphonium salts are also suitable catalysts [19].

Sterically hindered aromatic amines are treated with 2-fluoronitrobenzene in the presence of potassium fluoride at 180 °C [20].

Another process for the production of nitrodiarylamine compounds involves the treatment of 2-nitrochlorobenzene with an alkali-metal salt of a formanilide at 130 – 180 °C in a higher boiling alcohol. During the reaction, the formyl group is cleaved as carbon monoxide [21].

Finally, 2-nitrophenols are also suitable starting materials for the production of 2-nitrodiphenylamines. For example, 2,4-dinitrophenol is treated with phenyl isocyanate in the presence of potassium acetate in nitrobenzene for 6 h at 210 °C. 2,4-Dinitrodiphenylamine [*961-68-2*] is formed with loss of CO_2 [22]. The commercial name of the dye is Disperse Yellow 14.

From 2,4-dinitrochlorobenzene, Disperse Yellow 9 [*6373-73-5*] is obtained with *p*-phenylenediamine, and Disperse Yellow 1 [*119-15-3*] (**12**) with 4-aminophenol. Production of the latter is accelerated in the presence of a surface-active agent and a compound that forms metal complexes, such as ethylenediaminetetraacetic acid [23].

12

The dye is known under the following commercial names: Celliton Fast Yellow RR (BASF), Dispersol Fast Yellow A (ICI), Medurin Fast Yellow A (Mevisa), Navicet Fast Yellow RR (IDI), Serisol Fast Yellow A (Yorkshire Chemicals), Supracet Fast Yellow RR (Holliday), Tar Disperse Yellow B (Tarsus, Turkey).

A yellowish orange dye **13** is obtained by condensation of 1,4-dichloronitrobenzene with 4-anisidine [24]. The commercial name is Amacel Golden Orange 3 G (American Aniline).

13 [*6373-69-9*]

Mass spectrometric investigations show that 2-nitrodiphenylamines form more stable molecular ions than 4-nitrodiphenylamines. In the latter the nitro group is cleaved more readily. This is also the reason for the lower photostability of the 4-nitrodiarylamines [25]. Spectroscopic investigations show that the nitro dyes are mainly present in the quinoid form in the excited state [26].

The action of picryl chloride on a crown-ether-substituted aniline gives nitrodiphenylamines which are suitable for the colorimetric determination of potassium [27] and lithium ions [28].

Sublimation-resistant nitro disperse dyes are obtained by introduction of the sulfonamide group para to the amino nitrogen. The dye **14** colors acetate rayon and polyester materials greenish yellow.

14 [*1565-46-4*]

Commercial products: Amacel Yellow GLF (Koppers), Cibacet Yellow GL (Ciba-Geigy), Serisol Fast Yellow GGL (Yorkshire Chemicals).

The corresponding *N*-butyl sulfonamide [*70660-56-9*] is supplied commercially as Serisol Fast Yellow YGL (Yorkshire Chemicals) and as Supracet Fast Yellow AFG (Holliday).

If 1-chloro-2-nitrobenzenesulfonamide is treated with *p*-phenetidine, an ethoxy group is introduced into the position para to the amino nitrogen. The absorption maximum is thus shifted bathochromically.

Commercial products: Amacel Yellow 4 RLF (Koppers) Amacron Yellow RLS (American Aniline), Cibacet Yellow 4 RL (Ciba-Geigy), Samaron Fast Yellow RRL (Hoechst), Vondanyl Yellow 2 R (Vondelingenplaat).

The industrially most important nitro dye **15** is produced by treatment of 1-chloro-2-nitroben-

zene-4-sulfonyl chloride with two equivalents of aniline. The aromatic chlorine substituent is substituted and a sulfanilide is formed.

15 [*5124-25-4*]

An improved process for the production of **15** involves the treatment of 4-chloro-3-nitrobenzene-1-sulfonic acid with thionyl chloride at 70 – 80 °C to give the sulfonyl chloride, and its subsequent reaction with aniline in the presence of a surfactant at pH 7.5 – 12.5 in two stages at 5 – 50 °C and at 80 – 100 °C [29]. Calcium and magnesium carbonate have been proposed as acid-binding agents [30]. To improve the dyeing properties the dye has been converted into the heat-stable α-modification [31]. The resulting dye, Disperse Yellow 42, is contained in almost all product ranges for dyeing polyester. Dye mixtures that contain Disperse Yellow 42 as the yellow component have a particularly good exhaustion capacity on acetate fibers [32]. In 1990, 1100 t Disperse Yellow 42 were used for dyeing worldwide.

Commercial products include: Amacron Yellow LS (American Aniline), Cibacet Yellow GWL (Ciba-Geigy), Dianix Fast Yellow YL (Mitsubishi), Dispersol Fast Yellow T (ICI), Eastman Polyester Yellow ALSR (Eastman), Etalon Yellow GWL (Colorom), Foron Yellow SE-FL (Sandoz), Kayalon Polyester Yellow YL-SE (Nippon Kayaku), Miketon Polyester Yellow YL (Mitsui), Palanil Yellow GE (BASF), Polynal Yellow GSFD (National Aniline), Polyspers Yellow BT (Tenneco Chem.), Proxester Yellow GRL (Protex), Resolin Yellow GGLS (Bayer), Samaron Yellow 4 G (Hoechst), Serilen Yellow WLS (Yorkshire Chemicals), Sodyecron Yellow WLS (Southern Dyestuffs), Sumifix Yellow YGLN (Sumitomo), Terasil Yellow GWL (Ciba-Geigy), Tertranese Yellow P-GR (CKC/Tetre), Vondisperse Yellow ALS (Vondelingenplaat).

The dye produced analogously from *p*-toluidine has a color strength about 20 % higher [33]. A nitro dye with an oxyethylsulfonyl group para to the amino nitrogen is obtained by treatment of 1,4-phenylenediamine with 4-chloro-3-nitrophenyloxyethylsulfone [34].

Bifunctional nitro dyes are produced by reacting 1-chloro-2-nitrobenzene-4-sulfonyl chloride with ethylenediamine, followed by substitution of the aromatic chlorine by an aniline group [35].

16 [*25960-13-8*]

The reaction of dianisidine with 2 mol 2,4-dinitrochlorobenzene leads to the pigment **17** [36], known commercially as Mikrolith Brown 2 R-N (Ciba-Geigy).

17 [*29398-96-7*]

The 2,4-dinitrophenylhydrazone of 2,4-dihydroxyacetophenone **18** is also used as a nitro dye [37].

18 [*1166-12-7*]

Commercial product: Polysynthren Golden Orange 2 GSL (Cassella).

A hydrazone dye of the same type is obtained by coupling diazotized 2,4-dinitroaniline with α-acetyl-α-(4-bromophenyl)acetonitrile in aqueous ethanol, whereby the acetyl group is cleaved [38]. Yellow hydrazone dyes for polyesters are also obtained by coupling diazotized 2-nitroanilines, substituted by chlorine, methyl, or methoxy in the 4-position, with 4-nitrobenzylcyanide [39]. A nitro dye **19** of the hydrazone series with a heterocyclic end group is produced by coupling diazotized 2-nitroaniline with benzimidazolyl-2-acetamide [40].

19 [*2328-07-6*]

Commercial products: Palanil Yellow 4 GE (BASF), Ostacet Yellow SE-2 G (Chemapol), Rathilen Yellow 4 GE (Rathidye Chem).

5.2.2. Anionic Arylaminonitro Dyes

The first anionic nitro dyes were produced by treating picryl chloride with aromatic amino-sulfonic acids. However, only the product of the reaction of 2,4-dinitrochlorobenzene with 4-aminodiphenylamine-2-sulfonic acid (**20**, R = NO_2 [*15347-52-1*]) became important industrially [41].

20

This dye colors wool and polyamide fibers in lightfast yellow shades and has good leveling capacity. It is also used for one-bath dyeing and tanning of furs and fleeces [42].
Commercial products: Acidol Yellow-Brown GTE (BASF), Lurazol Fur Yellow E (BASF), Anthralan Yellow RRT (Hoechst), Coranil Brown HEPS (Hoechst), Apollo Acid Yellow-Brown EL (Taiheung), Lissamine Fast Yellow AE (ICI), Xylen Fast Yellow ES (Sandoz).

For dyeing wool and polyamide in yellow-brown shades, other derivatives of **20** are also suitable. For example the mixture of the two dyes with R = SO_2NH_2 [*72829-30-2*] and R = $SO_2NHC_6H_5$ [*72829-29-9*] is commercially available as Nylosan Yellow-Brown E-GL (Sandoz) [43]. Other dyes have been proposed for the same purpose, in which R is a sulfonate ester [44], carbonyl [45], or carboxylic acid amide group [46]. A commercial product from this series of dyes is Sella Acid Brown 5 GL (CibaGeigy). 2-Nitro-4′-aminodiphenylamine-4-sulfonic acid [*135-11-5*] is produced by condensation of the sodium salt of 4-chloro-3-nitrobenzenesulfonic acid with 1,4-diaminobenzene in saturated sodium chloride solution [47]. Inorganic salts of divalent metals (e.g., FeS) have also been proposed as catalysts [48]. The compound is commercially available as Coranil Brown HEPM new (Hoechst). Sulfonation of this compound affords 2-nitro-4′-aminodiphenylamine-2′,4-disulfonic acid, an intermediate for the production of acid nitrodiphenylaminoazo dyes (see Chap. 6.2) [49].

A bifunctional acid nitro dye **21** (C.I. 10 410, Acid Brown 13) can be produced by reacting 4,4′-dichloro-3,3′-dinitrodiphenyl sulfone with 4-aminodiphenylamine-2-sulfonic acid [50].

21 [*6373-79-1*]

Commercial product: Wofacid Fast Yellow-Brown 3 GL (Chemiekombinat Wolfen).

In the nitro dye **22**, which colors polyamide a brilliant greenish yellow, the conjugation is interrupted by CH_2 bridges between the aromatic rings [51].

22

Some nitro dyes are classified as reactive dyes. An example is the dye **23**, which gives a violet-brown shade on cellulose [52].

23 [*57975-30-1*]

For food dyeing it is desirable that the dye is not absorbed through the gastrointestinal tract. Polymeric nitro dyes such as **24** fulfil this requirement [53].

$n + m + p = 100–170$
$n = 1.3–1.7$

24 [*109563-84-0*]

5.2.3. Cationic Arylaminonitro Dyes

2-Nitrodiphenylamine-4-sulfonamides whose amide groups bear a cationic group are suitable for dyeing polyacrylonitrile [54].

25 [*4261-62-5*]

5.3. Heterocyclic Nitro Dyes

Polycyclic ring systems containing an NH group in one of the rings acquire the character of a nitro dye if they have a nitro group in the position neighboring the NH group. 4-Nitroacridone (**26**) is formed on heating 2-nitrodiphenylamine-2′-carboxylic acid with concentrated sulfuric acid in a ring-closure reaction [55].

26 [*4261-62-5*]

This dye is known commercially as Polynal Yellow NLA (National Aniline). Its resistance to sublimation is low. It can therefore be used to dye synthetic fibers by the transfer printing process [56].

The resistance to sublimation of nitroacridone dyes can be increased by the introduction of arylthioether groups [57]. The dye **27** colors

27 [*21810-30-0*]

polyester and polyamide yellow. Sublimationresistant acridone dyes are also obtained by introducing sulfonamide [58], sulfonate ester [59], and aryloxyalkylether groups [60].

Commercial products: Intrasil Yellow 2 GL (Intracolor), Terasil Yellow 2 GL (Ciba-Geigy).

Nitrophenoxazine and nitrophenothiazine dyes contain oxygen or sulfur, respectively, as the ring-closing member instead of the carbonyl group. They are also suitable for dyeing polyester fibers [61]. 2-Chloro-4-nitrophenoxazine dyes are produced by treating 1,4-dichloro-2,6-dinitrobenzene with 2-aminophenol derivatives in a polar organic solvent under alkaline conditions at 60 – 120 °C [62]. Under the same reaction conditions the 2,4-dinitrophenoxazine dyes are obtained with picryl chloride [63]. In both reactions a nitro group is cleaved during ring-closure.

Anionic heterocyclic nitro dyes are produced by reacting 2-aminophenol-4-sulfonic acids, which can be substituted in the 6-position by chloro, nitro, carboxyl, or sulfonic acid groups, with 2,4- [64] or 2,6-dinitrochlorobenzenes [65].

Nitrophenothiazine dyes are formed in the condensation of 2-aminothiophenol derivatives with 2,6-dinitrochlorobenzenes. Substitution at sulfur occurs initially, then a diphenylamine compound is formed by a Smiles rearrangement, and finally the phenothiazine ring closes with elimination of nitrous acid [66]. Nitro dyes of the phenazine series can be produced by reaction of 2,4,6-trinitroanisole or picryl chloride with 2,6-diaminodiphenylamine-4-sulfonic acids [67]. The dye **28** colors wool a lightfast brown. It was supplied commercially as Guinea Brown GRL.

28 [*6373-81-5*]

Some indazolones also belong to the heterocyclic nitro dyes. The dye **29**, for example, colors wool in fast brown shades.

29 [*70209-94-8*]

Commercial products: Kiton Fast Brown 2 RL, Neonyl Printing Brown 2 R (Ciba-Geigy).

6. Azonitro Dyes

Azonitro dyes are still important industrially because of their increased color strength compared to the dyes described above.

6.1. Azonitro Disperse Dyes

1,4-Phenylenediamine, after treatment with one equivalent of a halonitrobenzene, can then be diazotized and coupled with aromatic hydroxy compounds [68]. Besides 2,4-dinitrochlorobenzene, 2-nitrochlorobenzene compounds bearing a sulfonamide [69], carboxylic acid ester, or a carbonyl group [70] in the 4-position can be used as starting materials. Commercial products of this series are Serilen Golden Yellow R-FS (**30**) (Yorkshire Chemicals):

30 [*12217-97-9*]

and Sumikaron Yellow RS (**31**) (Sumitomo):

31

The hydroxyl group of the coupling component may be etherified [71] or esterified with benzenesulfonyl chlorides [72]. If the hydroxyl group is reacted with a polyether, a dye is obtained that colors polyester fibers from an aqueous liquor without previous dispersion [73].

1-Phenyl-3-methylpyrazol-5-one [74] and 2,6-dihydroxypyridine-4-carboxylic acid [75] are also possible coupling components.

The azo group can also be introduced by the reaction of 4-aminoazobenzene with halonitrobenzene compounds [76]. A further route to the introduction of nitro and azo components involves treating 2-nitrodiphenylamine-4-sulfonyl chloride with hydroxyazo dyes [77]. The nitro dye component can also be added on in the last stage by diazotizing and coupling 3-nitro-4-chloroaniline, and subsequently substituting the chlorine for an arylamino group [78].

6.2. Anionic Azonitro Dyes

For the production of anionic azonitro dyes, which are particularly suitable for dyeing polyamide materials, 1-chloro-2-nitrobenzene-4-sulfonic acid is treated with 1 mol 1,4-phenylene-diamine, diazotized, and coupled with aromatic hydroxy compounds [79]. The resulting dye (**32**, R = H, [*38455-53-7*]) is known commercially as Nylomine Yellow A-4 R (ICI) and Tertroxyl Fast Yellow 5 R (Crompton Knowles).

32

If the phenolic coupling component has a carboxyl group ortho to the OH group, the dye formed is particularly suitable for dyeing chromed leather, as it forms a chromium complex [80].

By alkylation of dyes which have been obtained by coupling with phenols [81] or naphthols [82], yellow or orange dyes are produced which color polyamide materials in very lightfast shades.

Esterification with *p*-toluenesulfonyl chloride gives a dye (**32**, R = $O_2S-C_6H_4-CH_3$, [*12220-06-3*]) which is contained in many product ranges for dyeing polyamide [83].
Commercial products: Kayanol Yellow N-3 R (Nippon Kayaku), Lanaperl Fast Yellow C-3 R (Hoechst), Nylanthren Yellow 3 RL (Althouse), Nylomine Orange C-G (ICI), Sandolan Golden Yellow MF-RL (Sandoz).

Besides the aromatic hydroxy compounds, amino compounds have also been reported as coupling components [84].

Anionic azonitro dyes with a sulfonic acid group on the central benzene ring are produced by treating *p*-phenylenediaminesulfonic acid with one equivalent of a halonitrobenzene, diazotization, and coupling to aromatic hydroxy compounds [85]. With *m*-cresol as the coupling component, the dye **33** is obtained which colors polyamide reddish yellow.

33

By etherification [86] or esterification [87] of the hydroxyl group, other dyes for polyamides are obtained.

A diazo component with two sulfonic acid groups can be produced by sulfonation of the product of the reaction of 2-nitrochlorobenzene-4-sulfonic acid with 1,4-phenylenediamine [88]. Diazotization and coupling with *o*-cresol gives an azonitro dye which colors polyamide fibers reddish yellow [89].

For synthetic polyamides, dyes are also used that have a sulfimide [90] or a sulfonamide group instead of a sulfonic acid group in the 4-position of the diphenylamine ring system. In the latter group of dyes the introduction of a sulfonic acid group either on the aromatic ring [91] or on the alkyl ether group is necessary to achieve sufficient solubility. This can involve either an alkanesulfonic acid group [92] or the sulfate ester of a hydroxyalkyl group [93].

34

Finally, the sulfonic acid can also be bonded via the sulfonamide group [94]. The dye **35** colors polyamide yellow.

35

Nitrodisazo dyes are produced by diazotization of 4-amino-2′-nitrodiphenylamine-4′-sulfonic acid and coupling with aminohydroquinone dimethyl ether, diazotization of the monoazo dye, and coupling with naphthol or naphthylaminesulfonic acids [95]. The following dye colors nylon black:

36 [*65612-07-9*]

1-Naphthylamine-6-sulfonic acid is also used as the middle component and 2-methylindole as the end component [96].

1-Chloro-2-nitrobenzene-4-hydroxyethylsulfone [34] is a starting material for the production of azonitro reactive dyes. After treatment with an aromatic [97] or aliphatic [98] diamine and conversion into the sulfate ester, the nitro dye is bonded to an azonitro reactive dye by treatment with an azo dye bearing a 2,4-dichloro-triazinyl group. The dye **37** contains two reactive groups and is used for level dyeing of mixtures of cotton with regenerated viscose fibers in a red shade.

37 [*105926-57-6*]

Disazonitro reactive dyes are obtained by bonding the nitro dye components described above once [99] or twice [100] with a disazo dye via the triazinyl ring. The dye **38** colors cellulose blue with a green cast. It has a high color strength and a very good exhaustion capacity.

38 [*107471-33-0*]

Nitro dyes have also been converted into nitrodisazo dyes by diazotization and coupling with monoazo dyes [101].

Nitroazo metal complex dyes are produced by diazotizing the product of the reaction between 2-nitrochlorobenzene-4-sulfonic acid and 1,4-phenylenediamine and coupling it with the monoazo dye from 2-amino-4-nitrophenol and resorcinol. After conversion to the 2 : 1 chromium complex, a brown leather dye is obtained [102]. To produce yellow-brown dyes for polyamide fibers and wool, the nitro dye from 2-nitrochlorobenzene-4-sulfonic acid and 1,4-phenylenediamine is treated with diketene to give the acetoacetamide, which is coupled with diazotized 2-amino-4-nitrophenol. The 2 : 1 cobalt complex dye **39** dyes wool with very good wet fastness [103].

39

6.3. Cationic Azonitro Dyes

Cationic azonitro dyes are obtained by treating a 1-chloro-2-nitrobenzene-4-sulfonamide, bearing a cationic substituent on the amide group, with an aminoazo compound. The cationic group can be a dialkylamino [104] or a trialkylammonium group [105]. The dye **40** colors polyacrylonitrile yellow with a red cast.

40 [*50567-78-7*]

7. Nitro Dyes with Other Color Systems

Anthraquinone nitro dyes have very low solubilities; most are pigments. By treatment of 3-nitro-4-chlorobenzoic acid amides with 1-aminoanthraquinone, pigments for coloring bulk plastics are formed [106]. The dye **41** colors PVC yellow.

41

A yellow pigment for dyeing polyolefins, polystyrene, and PVC is the nitroquinophthalone dye obtained by treating 7-amino-2,4-dimethylquinoline with cyanuric chloride and 2 mol 2-nitroaniline, followed by condensation with tetrabromophthalic anhydride [107].

8. Nitro Dyes in Hair Coloring

The major commercial use of nitrobenzene dyes, bearing amino or amino and hydroxy substituents, is in the dyeing of human hair.

The importance of nitro dyes for this use is shown by their accounting for about 30 % of the more than 4000 hair dye patents issued worldwide since 1900.

The development of semi-permanent hair colorants as a commercial category can be traced to the exploitation of the *N*-hydroxyalkyl derivatives of nitroanilines and diamino-nitrobenzenes which were first described in 1951 by Unilever [108].

Today, nitrobenzene dyes are used mainly in the so-called semipermanent hair dyes. These products employ a variety of derivatives of nitroanilines, diaminonitrobenzenes, and aminonitrophenols (see Table 2) together with certain aminoanthraquinones and azo dyes [109]. The early semipermanent colorants employed nitro dyes dissolved in an anionic shampoo base. Today, the dyes are generally dispersed or dissolved in a nonionic lotion which is applied directly to the hair and left for 20 – 40 minutes before rinsing. The dyes diffuse into the hair to give annular dyeing which withstands six to

Table 2. Nitro dyes used commercially in the United States

ten subsequent shampooings. The poor lightfastness, relative to normal textile dyes, is a consequence of their small molecular size. The latter property is of particular importance since it is necessary that the dyes should diffuse into the hair fiber at ambient temperature. Further, the poor wash fastness is of little disadvantage since the hair requires redyeing after four to six weeks due to the growth of new hair at the scalp.

In 1988, factory sales of hair colorant products in the United States exceeded $ 600 million. Of this, approximately 20 % was represented by semipermanent colorants containing nitro dyes.

The plethora of patents on nitrobenzene dyes for hair results in part from the fact that they represent the lowest molecular weight colored organic molecules, making them particularly suitable for dyeing at room temperature, and from the number of molecular structures that can be derived by N, O, or ring substitution of the six isomeric diaminonitrobenzenes and the ten isomeric nitroaminophenols.

In general, as can be seen from Table 2, the derivatives of *o*-nitroaniline and those of 2,5-didonor and 3,4-didonor substituted nitrobenzenes have been found to be the most useful. This can be ascribed to their ease of synthesis and to their superior lightfastness [110] compared to other isomers.

While a wide variety of O- and N-substituents have been examined, the most useful are evidently the hydroxyalkyl and methyl groups, appropriate combinations of which can be used to control solubility in the dye base and partition between the base and the hair.

A wide variety of reaction types, including direct nitration, selective reduction, electrophilic subsitution, alkylation, and molecular rearrangement are used in the manufacture of the commercially used nitro dyes.

8.1. Nitroaniline Hair Dyes

N-(2-hydroxyethyl)-2-nitroaniline (**43**) is employed as a yellow hair dye and is manufactured by heating 2-chloronitrobenzene (**42**) with monoethanolamine.

The 4-trifluoromethyl derivative of **43** has also found use and is similarly obtained from 2-chloro-5-trifluoromethylnitrobenzene [111].

8.2. Diaminonitrobenzene Hair Dyes

Three of the diaminonitrobenzenes, the 2,5-; 3,4-; and 2,4-isomers, have been used as hair dyes for about 90 years, although the last has rather poor lightfastness.

The red 2,5-isomer (**44**, $R^1 = R^2 = R^3 = H$) is obtained by nitration of *N,N′*-diacetyl-1,4-diaminobenzene, followed by hydrolysis, and is an important dye in the formulation of red and auburn shades.

The yellow 3,4-isomer (**45**, $R^1 = H$) is manufactured from 2,4-dinitrochlorobenzene by reaction with ammonia, followed by selective reduction of the 2-nitro group of the resulting dinitroaniline with sodium sulfide. The orange-yellow N^4-hydroxyalkyl derivatives of **45**, where R is 2-hydroxyethyl or tris(hydroxymethyl)methyl, are similarly obtained by using monoethanolamine or tris(hydroxymethyl)methylamine in place of ammonia.

The first of the blue-violet nitro dyes to be described was N^2,N^5,N^5-tris(2-hydroxyethyl)-2,5-diaminonitrobenzene (**48**, $R = CH_2CH_2OH$) and was originally obtained, in a somewhat impure state, by direct hydroxyethylation of 2,5-diaminonitrobenzene with 2-chloroethanol or ethylene oxide [108].

The development of a commercial synthesis for 4-fluoro-3-nitroaniline (**46**), involving low-temperature nitration of 4-fluoroaniline with fuming nitric acid in oleum [112], made possible the manufacture of **48** and other similar trisubstituted derivatives in a pure state. Hydroxyethylation of **46** to give the tertiary amine **47**, followed by reaction with a primary amine, is a convenient route to a variety of blue-violet dyes **48** [113]. The dyes **48** where R is 2-hydroxyethyl, methyl, ethyl, or 2,3-dihydroxypropyl have all found commercial use.

The bluish red dye **49** ($R = CH_2CH_2OH$) is obtained by reaction of 4-fluoro-3-nitroaniline with monoethanolamine, while reaction with methylamine gives the similar dye **49** ($R = CH_3$) [113].

A method for the introduction of a single *N*-hydroxyethyl group onto the 5-amino group of a 2,5-diaminonitrobenzene, e.g., **50**, involves the reaction of the amine with 2-chloroethylchloroformate and treatment of the resulting carbamate **51** with potassium hydroxide in aqueous ethanol [114] to give the bluish red dye **52**. A similar reaction can be used to introduce a 2-hydroxyethyl group onto the 2-amino group, provided that the 5-amino group is first blocked by acetylation [115].

These reactions involve the intermediate formation of the aminonitrophenyloxazolidone and have been used in the synthesis of N^2,N^5-disubstituted-2,5-diaminonitrobenzenes [116].

Reaction of 4-fluoro-3-nitroaniline (**46**) with 2-chloroethylchloroformate gives the carbamate **53**, which is cyclized to **54** by the action of sodium methoxide in methanol. The oxazolidone **54** is then reacted with a primary amine to give the intermediate **55** which, on alkaline hydrolysis, gives the violet diaminonitrobenzene dyes **56**, where R is alkyl or hydroxyalkyl.

Two other commercially used blue-violet dyes **58**, where R = 2-hydroxyethyl or 2,3-dihydroxypropyl, are obtained by direct hydroxyalkylation of N^2,N^5-dimethyl-2,5-diaminonitrobenzene (**57**) with 2-bromoethanol in the presence of calcium carbonate [117], or with glycidol [118], respectively. The starting material **57** is made by reaction of the N^5-acetyl-N^5-methyl-N^2-tosyl compound with dimethyl sulfate, followed by conventional detosylation and hydrolysis [119]. It can also be obtained by methylation of the N^2,N^5-ditosyl derivatives of 2,5-diaminonitrobenzene with dimethyl sulfate, followed by detosylation with concentrated sulfuric acid [120], or by direct methylation with a mixture of formaldehyde and sulfuric acid at 40 – 120 °C [121].

8.3. Aminonitrophenol Hair Dyes

Five of the ten isomeric aminonitrophenols are used in hair dyes. Four of these, 2-amino-4-nitrophenol, 2-amino-5-nitrophenol, 4-amino-2-nitrophenol, and 4-amino-3-nitrophenol are commodity chemicals used in textile dye synthesis. The fifth, 2-amino-3-nitrophenol, is prepared by nitration of 2-acetoxyacetanilide with nitric acid in acetic anhydride at low temperature [122], followed by hydrolysis.

The first N-substituted aminonitrophenol to be employed in hair dyeing was *N*-methylisopicramic acid **59** which can be made by nitration of *N*-acetyl-*N*-methyl-4-aminophenol or, more conveniently, by nitration with nitric acid of a cold solution of 4-*N*-methylaminophenol in concentrated sulfuric acid [123]. Picramic acid (**60**) is made by the selective reduction of picric acid with sodium sulfide.

O,*N*-Bis(2-hydroxyethyl)-2-amino-5-nitrophenol **61**, which was originally listed in official compendia as the *N*,*N*-bis(2-hydroxyethyl) compound [124], is prepared by direct hydroxyethylation of 2-amino-5-nitrophenol with 2-chloroethanol in the presence of sodium hydroxide as an acid binder. A less convenient multistep synthesis has also been described [122].

A similar yellow dye, *N*-(2-hydroxyethyl)-2-amino-5-nitroanisole **62** is obtained by the action of 2-bromoethanol on 2-amino-5-nitroanisole [125].

The red dye *N*-(2-hydroxyethyl)-4-amino-3-nitrophenol (**63**, R = H) is manufactured by the reaction of 4-amino-3-nitrophenol with 2-chloroethylchloroformate in dioxane with calcium carbonate as an acid binder. The intermediate carbamate is converted to **63** (R = H) by the action of aqueous potassium hydroxide, from which the potassium phenolate precipitates. The free phenol is precipitated by neutralizing an aqueous solution of the phenolate with hydrochloric acid [126].

The methyl ether **63** ($R = CH_3$) has also found use as an orange-red dye and is obtained by the action of ethylene oxide on 4-amino-3-nitroanisole in aqueous acetic acid at ambient temperature [127]. 1-(3-Methylamino-4-nitrophenoxy)propane-2,3-diol (**64**, $R = CH_2CHOHCH_2OH$) is reported to be more soluble in typical semipermanent dye bases than the previously used anisole derivative ($R = CH_3$). The yellow dye is made by the slow addition of 3-*N*-methylamino-4-nitrochlorobenzene to a solution of sodium hydroxide in glycerol at about 120 °C [128]. A similar reaction with ethylene glycol gives the analogue **64** ($R = CH_2CH_2OH$) [129].

8.4. Nitrodiphenylamine Hair Dyes

Two nitrodiphenylamine dyes have been found to be particularly useful in semipermanent hair colorants.

65

66

The red dye 4-amino-2-nitrodiphenylamine (**65**) is manufactured by the reaction of 4-fluoro-3-nitroaniline with aniline in the presence of calcium carbonate as an acid scavenger [130].

A yellow dye, 4-hydroxy-2′-nitrodiphenylamine (**66**), is obtained by the reaction of 2-chloronitrobenzene with 2-aminophenol [131].

8.5. Formulation with Nitro Hair Dyes

While relatively unreactive, the nitro dyes employed in semipermanent hair colorants cannot be regarded as completely inert if an adequate shelf-life for the product is to be attained.

A wide range of nonionic or anionic surfactants have been found to be compatible with the dyes, particularly fatty alkanolamides and ethoxylated fatty alcohols.

Dyeing is best achieved at alkaline pH, and the choice of alkalizing agent has been found to be important. Dyes having a secondary amino group ortho to the nitro group cannot be used in formulations containing ammonia due to a facile amine exchange reaction; e.g., the conversion of **68** to **67** occurs within weeks at ambient temperature [132].

67 **68** **69**

A more remarkable reaction has been found to occur when diaminonitrobenzenes are stored in the presence of monoethanolamine (MEA). An amine exchange reaction is followed by a series of oxidation/reduction steps resulting in the formation of 6-aminoquinoxalines **69** [132]. The reaction appears to be quite general and occurs with 2,4- and 3,4-diaminonitrobenzenes as well as the 2,5-isomers.

These reactions can be avoided by the use of other alkanolamines such as diethanolamine and aminomethylpropanol [133].

The problem of poor solubility of the nitro dyes in cosmetically acceptable lotion bases has been met in part by the use of dyes bearing hydroxyalkyl substituents. In particular, the dye N^2,N^5-dimethyl-N^5-(2,3-dihydroxypropyl)-2,5-diaminonitrobenzene (**58**) ($R = CH_2CHOHCH_2OH$) can cosolubilize similar dyes such as those of structure **48** where R is alkyl or hydroxyalkyl [134].

Some nitro dyes have been found to be subject to air oxidation. Antioxidants, particularly ascorbic acid or erythorbic acid, which do not reduce the nitro group, are generally added to the formulations [135].

9. Biologically Active Nitro Dyes

A whole series of compounds with nitro dye character are used in plant protection or have

pharmaceutical activity. Of the hydroxynitro compounds, 3,5-dinitro-*o*-cresol is used as a herbicide. Alkylanilines containing nitro groups (e.g., **70**) [136] and *N*-alkyl derivatives of nitro-*m*-phenylenediamines (e.g., **71**) [137] also exhibit herbicidal effects.

70

71

Nitro-*m*-phenylenediamine compounds with *N*-(aminoalkyl) substituents such as **72** are suitable for the therapy and prophylaxis of various viral infections [138].

72

2-Nitro-4-trifluoromethyldiphenylamines bearing a substituted alkyl ether group in the 4′-position are used as herbicides [139], for example **73**.

73

The introduction of a thiophosphate ester into the 4′-position gives diphenylamine compounds with insecticidal and miticidal properties [140]. 2,4-Dinitro-6-trifluoromethyldiphenylamine compounds with fluorine-containing substituents in the second phenyl ring are used as algicides for the protection of ships' hulls [141], as herbicides (e.g., **74**) [142], and as insecticides [143].

74

2,6-Dinitro- and 2,4,6-trinitrodiphenylamine compounds have fungicidal properties [144]. Pyridylnitrophenylamines bearing trifluoromethyl groups are used as insecticides [145]. An example is:

75

The corresponding pyrimidyl compounds are suitable for the same purpose [146].

76

Nitroacridine compounds such as **76** inhibit tumor formation [147].

10. Nitroso Dyes

Hydroxynitroso compounds are formed by the action of nitrous acid on phenols and naphthols. These nitroso compounds are not themselves dyes, but are capable of forming metal complexes that are either pigments or, if the starting compound bears hydrophilic groups, are acid dyes.

The iron(II) complex of 1-nitroso-2-naphthol (Pigment Green B) is used for wallpaper and disperse paints because of its lightfastness [148].

77

The pigment properties of **77** are improved by the addition of dimethylphenylbenzylammonium chloride in an alkaline soda medium before complex formation [149]. Pigment Green B absorbs light of wavelength 650 – 850 nm, λ_{max} = 730 – 750 nm. It is therefore suitable for the production of recording inks that are read

by using IR radiation [150] and for data storage with a semiconductor laser [151]. Pigment Green B is also used for coloring rubber [152]. The toxicity of Pigment Green B is low: LD_{50} (oral) = 5000 mg/kg. Skin and eye irritation have not been observed.

The nickel complex of 1-nitroso-2-naphthol is also in use [153]. It is known commercially as Monarch Gold X 3306 (Hercules). Naphthol Green B, the sodium salt of the iron complex of 1-nitroso-2-naphthol-6-sulfonic acid, is suitable for dyeing wool, silk, and paper. Its commercial name is Basovit Green 971 (BASF). The dye is also used for the production of IR-absorbing inks [154] and polarizing filters [155]. When precipitated with barium salts, Naphthol Green B is used for coloring paints.

The iron complex of 2-nitroso-1-naphthol-4-sulfonamide is used for dyeing and printing polyamide and polyurethane fibers in green shades [156].

1-Nitroso-2-hydroxynaphthalene-3-carboxylic acid amides whose amide groups have cationic substituents can be transformed by metallization into lightfast cationic complex dyes, which are suitable for dope dyeing of polyacrylonitrile fibers and for dyeing leather [157].

Heterocyclic compounds are also used for the production of nitroso dyes, examples of which include iron complexes of 5-nitroso-6-hydroxy-quinoline [158], 6-hydroxy-7-nitrosobenzothiazole [159], 1-methyl-4-nitroso-5-hydroxybenzimidazole [160], and 3-chloro-6-hydroxy-7-nitrosoindazole [161].

Open-chain compounds obtained by nitrosation of acetoacetic acid arylamides also belong to the nitroso dyes. Particularly useful pigments are obtained if the nitrosated acetoacetic acid arylamide is first converted to the oxime with hydroxylamine and the nickel complex is then formed [162]. The complex **78** is a lightfast yellow pigment for printing inks, varnishes, or plastics.

78

Commercial products: Paliotol Yellow 3 R, Luconyl Yellow 3 R (BASF).

1. Introduction

Aliphatic nitro compounds (RNO_2), also called nitroalkanes and nitroparaffins, are isomeric with the chemically different alkyl nitrites (RONO). As shown by the following equilibrium involving a secondary nitroalkane, the nitroalkane and nitronic acid are tautomers, sharing a common nitronate anion.

The nitroalkane is less acidic than the corresponding nitronic acid and, in most cases, the equilibrium lies far to the left. The acidity of the primary and secondary nitroalkanes is due partly to the electron-withdrawing effect of the nitro group and the resonance stability of the nitronate anion.

2. Properties

Physical Properties. The four nitroalkanes of greatest industrial significance, nitromethane [*75-52-5*], CH_3NO_2; nitroethane [*79-24-3*], $CH_3CH_2NO_2$; 1-nitropropane [*108-03-2*], $CH_3CH_2CH_2NO_2$; and 2-nitropropane [*79-46-9*], $CH_3CH(NO_2)CH_3$ are all colorless liquids when pure. Nitroalkanes are only slightly soluble in water. Due in part to its polarity, the nitro group causes a large increase in flash point and boiling point compared to the corresponding hydrocarbon. Nitroalkanes are often useful because they readily form azeotropes with many organic solvents such as alcohols, ketones, and hydrocarbons [1]. The physical properties of the four basic nitroalkanes are listed in Table 1 (see next page).

Chemical Properties. Primary and secondary nitroalkanes are excellent building blocks for the synthesis of more complex molecules, since the readily formed nitronate anion undergoes many useful condensation reactions. Especially important is the condensation of these anions with aldehydes and ketones (Henry reaction) [3–8], and the Michael reaction, in which the nitronate anion reacts with α,β-unsaturated carbonyl compounds, nitriles, esters, and other activated alkenes [9–12]. The following is an example of the Henry reaction:

A typical Michael addition is shown as follows:

Figure 1 shows how nitroalkanes can be employed to make more complicated molecules.

The nitro group can subsequently be transformed into a variety of other functional groups, as illustrated in Figure 2. Thus, nitroalkanes allow the precise placement of these functional groups into complex structures. The chemistry depicted in Figures 1 and 2 (see next pages) is discussed in detail in [2, 13–18].

3. Production

For more than forty years, the four principal nitroalkanes have been produced by the high-temperature vapor-phase nitration of propane [19]. The process, which employs nitric acid as the nitrating agent, is based on a free radical reaction, in which the active species is the NO_2 radical. This procedure produces a nitroalkane mixture rich in nitropropanes. The process is used by Angus Chemical Company for bulk production of nitromethane, nitroethane, 1-nitropropane, and 2-nitropropane.

The reaction is carried out at 350 – 450 °C. At this temperature all participants in the reaction are gaseous. The reaction is fast but not too fast, so that good temperature control is still assured. The pressure is adjusted to 0.8 – 1.2 MPa, so that the reaction product leaving the reactor can be condensed without liquefying the hydrocarbon. The temperature of the exothermic reaction can be controlled in various ways:

1) By using an excess of propane to remove the heat, the molar ratio of propane to nitric acid being at least 4 : 1;

Figure 1. Building new chemicals with nitroalkanes

Figure 2. Functional group transformations

2) By spraying liquid nitric acid into the heated propane, the heat of reaction being used to vaporize nitric acid and to produce nearly adiabatic conditions;
3) By using 60 – 70 % nitric acid, thus producing a large volume of steam, which acts as an inert medium in the reactor; or
4) By controlling the temperature in the reactor via the residence time, the shorter the residence time the lower being the temperature. Short residence time is also important for maximum formation of nitroalkane and minimum formation of byproducts.

The vapor-phase nitration of propane by nitric acid proceeds mainly by a free radical mechanism. The decomposition of the nitric acid to ·OH and ·NO_2 or ·ONO, the postulated initiating step, requires temperatures above 350 °C.

By reaction of the OH radicals with alkanes, alkyl radicals can be formed, which then react further with NO_2 radicals to give nitroalkanes. However, the alkyl radicals can also react with HNO_3 to form nitroalkane and •OH and in that way continue the chain. The most important side reaction of the alkyl radical is the formation of nitrite, which is unstable at the reaction temperature and decomposes to nitric oxide and an alkoxy radical.

$$R\cdot + \cdot ONO \longrightarrow RONO$$

$$RONO \longrightarrow RO\cdot + NO$$

Alkoxy radicals can decompose with cleavage of the carbon – carbon bond and formation of alkyl radicals of lower molecular weight.

$$R'CH_2O\cdot \longrightarrow R'\cdot + CH_2O$$

This can explain the formation of nitroethane and nitromethane during the nitration of propane. Other byproducts of this process are alcohols, aldehydes, ketones, and related oxygen-containing derivatives.

The conversion of nitric acid to nitroalkanes in vapor-phase nitration is less than 50 %. An improved conversion can be achieved by adding a small amount of oxygen or halogen. This is not done in the industrial process, however, since addition of oxygen promotes the formation of large amounts of oxygen-containing byproducts, whereas with halogen addition, corrosion problems or difficulties with the processing of the reaction mixture can occur.

Most of the nitric acid is converted to NO, NO_2, N_2O, and N_2; NO and NO_2 are recovered. The overall loss of nitric acid is 20 – 40 %.

Excess propane is sometimes also recovered from the reactor liquid and reused, so that about 60 – 80 % of the propane reacts to give nitroalkanes.

Rapid cooling immediately after the nitration leads to liquefaction of the nitroalkanes and the oxygen-containing byproducts. The liquid and gas phases are separated, and after propane and nitrogen oxides have been recovered from the gas phase they are returned to the reactor. Some of the byproducts, e.g., formaldehyde, are removed by separation of the aqueous phase. The low-boiling oxygen-containing byproducts such as acetaldehyde or acetone, and nitrogen-containing byproducts such as acetonitrile, can be separated as distillation first runnings from the organic phase. The nitroalkanes so obtained are subjected to a chemical washing process (to remove dissolved higher-boiling oxygen-containing impurities) and then washed with water. The remaining water is removed by passing through a drying tower, and the individual nitroalkanes are then obtained as pure products by fractional column distillation.

More recently, a number of publications have been issued describing improved methods for the syntheses of nitroalkanes [20–25]. However, in the past few years only one major new nitroalkane plant has been placed in operation, the W. R. Grace & Co. facility in Deer Park, Texas. The new Grace process employs a mixture of ethane and propane for the hot-tube, free-radical process, and uses N_2O_4 as the source of NO_2. This process produces a nitroalkane mixture richer in nitromethane and nitroethane.

4. Quality Specifications and Analysis

The specifications for the four nitroalkanes produced at the Grace plant in Texas are given in Table 2. Purity and total nitroalkane content are assayed by capillary gas chromatography; water content is measured by typical Karl Fischer procedures. The acidity is determined by dissolving

Table 2. Product specifications of the four common nitroalkanes (W. R. Grace & Co.)

Specification	Nitromethane	Nitroethane	1-Nitropropane	2-Nitropropane

Relative density at 25 °C	1.124 – 1.129	1.042 – 1.047	0.997 – 0.999	0.984 – 0.988

∗ A special grade of nitroethane is available with > 99 % purity.

the nitroalkane in methanol and titrating with dilute sodium hydroxide with bromocresol green as indicator.

5. Storage and Transportation

Nitroalkanes can be safely stored and transported, but certain precautions should be observed with respect to their shock sensitivity. It is necessary to protect nitroalkanes from extremes of temperature and pressure, e.g., fire and shock, and from chemical contamination which could further sensitize them to these extremes. Although the four commercial nitroalkanes are relatively insensitive to detonation by shock at ordinary temperatures, their sensitivity increases with increasing temperature. The tendency of the nitroalkanes toward detonation is inversely related to chain length. Nitromethane presents the most serious shock-sensitivity hazard of the four common nitroalkanes.

Adiabatic compression also poses a special problem in the handling of nitromethane. Thus, the transfer of nitromethane via pumps and piping requires special conditions designed to avoid adiabatic compression [1].

In addition, special care must be taken to avoid forming dry alkali-metal salts of the nitroalkanes, especially in the case of nitromethane. For example, in the presence of a strong base, such as sodium hydroxide, nitromethane can form the sodium salt of methazonic acid (2-nitroacetaldehyde oxime) which, when dry, is very shock sensitive and can explode. Mixtures of nitromethane and an amine and/or heavy metal oxides, such as those of silver, lead, and mercury, can lead to violent decompositions and should be avoided.

Nitromethane is packaged in 55-gallon drums to a net weight of 500 lb. The drum headspace is filled with nitrogen to exclude moisture and to reduce the hazard of adiabatic compression during transportation. The drums are thin-walled so that they rupture easily in the event of high energy impact. Nitromethane drums should not be stacked, but stored on-end in a single layer.

Nitroethane, 1-nitropropane, and 2-nitropropane are also transported in 55-gallon drums under nitrogen. However, because these nitroalkanes are not as shock sensitive as nitromethane, there are no special restrictions on stacking drums.

Nitroethane, 1-nitropropane, and 2-nitropropane are also available neat in bulk quantities transported in tank wagons or rail cars. Bulk nitromethane presents special hazards and, in the United States, may not be transported undiluted in containers having a capacity greater than 110 gallons (ca. 416 L). Nitromethane, however, can be transported in bulk when mixed with any of a variety of approved diluents. The following diluents, along with their minimum content in wt %, have been approved for the transportation of nitromethane: 1,2-butylene oxide (40 %), cyclohexanone (25 %), 1,4-dioxane (35 %), methanol (45 %), 1,1,1-trichloroethane (50 %), 1-nitropropane (48 %), and 2-nitropropane (47 %). These bulk nitromethane mixtures are safely transported by road and ocean freight. All of the nitroalkanes should be kept away from oxidizing, corrosive, or sensitizing materials.

For more details on storage and transportation procedures, refer to a nitroalkane safety guide [1].

6. Uses of Nitroalkanes and their Derivatives

6.1. Nitromethane and Derivatives

One of the most important uses for nitromethane in which it is used without chemical modification is the stabilization of halogenated hydrocarbons. For example, small amounts of nitromethane (and sometimes nitroethane and/or 1-nitropropane) are widely used in industry to form stable noncorrosive mixtures with 1,1,1-trichloroethane that are used in vapor degreasing, dry cleaning, and for cleaning semiconductors and lenses. These nitroalkanes are useful for inhibiting corrosion on the interiors of tin-plated steel cans containing water-based aerosol formulations. Nitromethane is also employed to stabilize the halogenated propellants for aerosols.

Nitromethane is frequently employed as a polar solvent for cyanoacrylate adhesives and acrylic coatings. Nitromethane is also used for cleaning electronic circuit boards; nitroethane and nitropropanes are also used for this purpose. Nitromethane alone, and in mixtures with

methanol and other nitroparaffins, is used as a fuel by professional drag racers and hobbyists. Hobbyists use the nitromethane-based fuel primarily for radio-controlled aircraft. The explosives industry utilizes nitromethane in a binary explosive formulation. The liquid (nitromethane) and solid (inorganic nitrate) ingredients are safely transported and stored separately as standard commercial products. When mixed, an explosive more energetic than 60 % dynamite is formed. There are also commercial and military applications for nitromethane in shaped charges, which are often used for targeted undersea explosions and line trenching.

Nitromethane Derivatives. *Chloropicrin* [*76-06-2*], trichloronitromethane, Cl_3CNO_2 can be prepared by the reaction of nitromethane with sodium hypochlorite. This chlorinated nitro compound is an effective fungicide and nematocidal fumigant.

Tris(hydroxymethyl)nitromethane [*126-11-4*], [2-(hydroxymethyl)-2-nitro-1,3-propanediol], $(CH_2OH)_3CNO_2$ is obtained if three moles of formaldehyde react with nitromethane via the Henry reaction. This derivative is used as a biocide.

Tris(hydroxymethyl)aminomethane [*77-86-1*], [2-amino-2-(hydroxymethyl)-1,3-propanediol], $(CH_2OH)_3CNH_2$ is prepared by reduction of tris(hydroxymethyl)nitromethane. It is used industrially as a buffer and as a component in adhesives and resins.

The addition of two moles of formaldehyde to nitromethane by the Henry reaction gives di(hydroxymethyl)nitromethane $(CH_2OH)_2CHNO_2$, which can be converted to the corresponding amino compound, $(CH_2OH)_2CHNH_2$ (2-amino-1,3-propanediol) [*1794-90-7*]. This amine is employed in the synthesis of the X-ray contrast agent Iopamidol [26].

The brominated product $(CH_2OH)_2CBrNO_2$ (2-bromo-2-nitro-1,3-propanediol) [*52-51-7*], which can be derived from di(hydroxymethyl) nitromethane is a widely used biocide (Bronopol).

The reaction between benzaldehyde and nitromethane does not stop at the corresponding nitroalcohol; instead, dehydration to β-nitrostyrene, $C_6H_5CH{=}CHNO_2$ [(2-nitroethenyl)-benzene] [*102-96-5*], occurs. This nitroalkene has been used as a chain transfer agent, i.e., to lower the molecular weights of polymers in their free radical initiated synthesis.

Treatment of β-nitrostyrene with bromine, followed by dehydrobromination, gives bromonitrostyrene, $C_6H_5CH{=}CBrNO_2$ [(2-bromo-2-nitroethenyl)benzene] [*7166-19-0*], which is employed as a slimicide.

An important use of nitromethane is in the synthesis of the anti-ulcer drugs Nizatidine [27] and Ranitidine [28]. A commercial route to Ranitidine is shown below [29]:

Finally, nitromethane is used in the preparation of the psychotropic agent Sulpiride [30].

6.2. Nitroethane and Derivatives

Nitroethane is employed as a solvent due to its excellent wetting properties and its ability to form azeotropes with many industrial solvents. For example, some printing inks contain nitroethane.

Nitroethane is used by the commercial blasting industry as either a fuel or sensitizer of water-based blasting agents. Nitroethane can be added to nitromethane to reduce its tendency to detonate when used as a fuel in internal combustion engines.

Nitroethane Derivatives. The Henry reaction between two moles of formaldehyde and nitroethane gives 2-methyl-2-nitro-1,3-propanediol [*77-49-6*], $CH_3CNO_2(CH_2OH)_2$ which is utilized as a biocide in cutting oils.

Catalytic hydrogenation of 2-methyl-2-nitro-1,3-propanediol affords the corresponding amine, 2-amino-2-methyl-1,3-propanediol [*115-69-5*]. After reaction with oleic acid, this aminoalcohol forms an oxazoline [31], which is used as a specialty cationic surfactant.

Nitroethane is used to make a plasticizer for solid rocket fuels [32]. The molecuar structure for this plasticizer is:

The antihypertensive drug Aldomet (methyl DOPA) is made using nitroethane. The synthesis follows the general route [33, 34]:

6.3. 1-Nitropropane and Derivatives

Like the other basic nitroalkanes, 1-nitropropane is employed as a solvent or cosolvent.

The most important use for 1-nitropropane is in the synthesis of Ethambutol, an antituberculosis drug [35].

Only the D-enantiomer of 2-amino-1-butanol is used in the final synthetic step.

Relatively small quantities of 1-nitropropane are used in the preparation of biocides [36].

6.4. 2-Nitropropane and Derivatives

A major use of 2-nitropropane is as an industrial solvent. It is used in vinyl inks that are employed in printing, flexography, and photogravure. The 2-nitropropane, often mixed with alcohols, dissolves a large number of resins such as epoxy, polyurethane, polyester, vinyl, urea–formaldehyde, and phenolic. These solvent–resin mixtures are used for coatings. For example, can-coating varnishes contain the nitroalkane because of its excellent wetting properties. Other applications of these 2-nitropropane formulations are in adhesives and in electrostatic paints. Some of the properties of 2-nitropropane that make it so versatile in many of these applications are: high polarity and flash point, appropriate evaporation rate, good wetting and azeotropic properties, and satisfactory resistivity.

2-Nitropropane Derivatives. The Henry reaction of 2-nitropropane with formaldehyde yields 2-methyl-2-nitro-1-propanol (NMP) [*76-39-1*].

This nitroalcohol has been employed as an adhesive component to improve tire cord bonding [37].

Catalytic hydrogenation of NMP affords 2-amino-2-methyl-1-propanol (AMP) [*124-68-5*]. This aminoalcohol is a useful organic base for neutralizing and solubilizing applications. Other applications of AMP are:

1) AMP is used in toiletries, cosmetics, and in hair sprays, in which it neutralizes and solubilizes the carboxyl-containing polymers used in their formulation.
2) In conjunction with fatty acids, AMP is an excellent dispersing agent for powders and pigments, especially titanium dioxide.

3) AMP has been employed as a formaldehyde scavanger in melamine – formaldehyde, urea–formaldehyde, and phenol – formaldehyde resins.
4) AMP has also been used as a wetting agent, as an emulsifier in polishing waxes, and in textiles for permanent pleats.

Finally, 2-nitropropane has been utilized in the preparation of the experimental β-blocking drug, Bucindolol, [38–40], whose synthesis scheme shows how 2-nitropropane can be used to introduce a *tert*-butylamine functionality into a molecule:

7. Toxicology and Occupational Health

The two most important health controls for nitroalkane exposure are adequate ventilation and prevention of skin contact.

In the United States, OSHA and ACGIH have set PE's and TLV's for the nitroalkanes [41,42]. The OSHA and ACGIH limits are shown in Table 3, together with MAK values.

Table 3. Industrial exposure limits for nitroalkanes, mL/m^3 (ppm)

Compound	PEL (OSHA)	TLV (ACGIH)	MAK
Nitromethane	100	100	100
Nitroethane	100	100	100
1-Nitropropane	25	25	25
2-Nitropropane	25	10	*

* Identified as a suspected human carcinogen; safe exposure limit has not been established.

Inhalation is the major industrial hazard of nitroalkane exposure. The reported effects of overexposure to vapors are headache, nausea, vomiting, and convulsions. Although chronic exposure to animals indicates some liver and kidney injury, no such injury has been reported in humans when exposures were maintained below the TLV levels.

Nitroalkane vapors can cause eye irritation at levels above the recommended TLVs. Since the nitroalkanes' odor detectabilities are poor, odor detection does not serve as a warning for overexposure. Therefore, prolonged exposure to vapors above the TLV necessitates the use of respirators. Such exposure may occur in operations that require entry into tanks or closed vessels and in emergency situations. Acute exposure to extremely high concentrations of 2-nitropropane vapors has resulted in serious injuries and, in some cases, death when workers were exposed in enclosed spaces without using recommended respiratory protection or adequate ventilation. For respiratory protection, supplied-air or self-contained breathing apparatus with a full facepiece should be used.

Nitroalkanes are mild skin irritants due to their solvent action but are not absorbed through the skin. Although irritation can occur from prolonged or repeated skin contact, no allergic or sensitization reactions have been reported.

The acute LD_{50} (rat, oral) of the nitroalkanes is as follows [43]:

Nitromethane	1210 ± 322 mg/kg
Nitroethane	1620 ± 193 mg/kg
1-Nitropropane	455 ± 75 mg/kg
2-Nitropropane	725 ± 160 mg/kg

The National Toxicology Program of the U.S. Department of Health and Human Services, The International Agency for Research on Cancer, and the American Conference of Governmental Industrial Hygienists list 2-nitropropane as a suspect carcinogen. The classification is based on studies in which prolonged exposure to 2-nitropropane was found to cause liver neoplasms in laboratory rats [44].

In 1979, an epidemiological study of workers exposed to 2-nitropropane was reported by the International Minerals and Chemical Corporation. The authors concluded that analysis of these data does not suggest any unusual cancer or other disease mortality pattern among this

group of workers [45]. There is no evidence that 2-nitropropane causes cancer in humans.

1. Introduction

The earliest aromatic nitro compounds were obtained by MITSCHERLICH in 1834 by treating hydrocarbons derived from coal tar with fuming nitric acid. By 1835 LAURENT was working on the nitration of naphthalene, the most readily available pure aromatic hydrocarbon at that time. DALE reported on mixed nitro compounds derived from crude benzene at the 1838 annual meeting of the British Association for the Advancement of Science. Not until 1845, however, did HOFMANN and MUSPRATT report their systematic work on the nitration of benzene to give mono- and dinitrobenzenes by using a mixture of nitric and sulfuric acids.

The first small-scale production of nitrobenzene was carefully distilled to give a yellow liquid with a smell of bitter almonds for sale to soap and perfume manufacturers as "essence of mirbane."

Bechamp's iron reduction process, which made aniline more readily available, was published in 1854, and the discovery of aniline mauve by PERKIN in 1856 started the European aniline dye industry that became the basis for a worldwide synthetic colorant industry estimated to have had sales of $\$ 6 \times 10^9$ in 1988.

Process development and scaleup of the nitration and reduction processes, begun by PERKIN and continued by many others, resulted in the trade price of aniline dropping from 50 Fr/kg in 1858 to 10 Fr/kg in 1863; by 1871, the European production of aniline had reached 3500 t/a [23].

In 1985 European production of aniline was 500 000 t/a, and it is still the single largest product based on a nitration process. Its use in colorants now accounts for only 4 % of aniline pro-

10.1002/14356007.a17_411

duction because most of the growth has been due to rubber chemicals and isocyanates, the latter now consuming well over 50 % of nitrobenzene production for the manufacture of methylene diphenyldiisocyanate.

The number of naturally occurring nitroaromatic compounds is small; the first to be recognized was chloramphenicol (**1**), an important compound extracted from cultures of a soil mold *Streptomyces venezuelae* and identified in 1949.

1

This discovery stimulated investigations into the role of the nitro group in pharmacological activity, following the earlier (1943) discovery of the antibacterial activity of nitrofuran derivatives. Many synthetic pharmaceuticals and agrochemicals contain nitroaromatic groups, although the function of the nitro group is often obscure.

Nitration is the dominant method for introducing the nitro group into aromatic systems. Several so-called indirect methods also exist:

1) Oxidation of nitroso or amino compounds,
2) Replacement of diazonium groups (nitro-Sandmeyer reaction),
3) Rearrangement of nitramines, and
4) Nucleophilic displacement reactions.

Although useful in overcoming problems of substituent orientation or substrate sensitivity to nitration conditions [14], they have very little industrial significance. Of more than 200 nitroaromatic compounds described in this article, only two require synthesis by indirect methods. Many important nitro compounds are produced by applying unit processes (e.g., sulfonation, halogenation, or amination) to primary nitro starting materials, most of which are derived from the key primaries nitrobenzene, nitrotoluenes, and nitrochlorobenzenes.

Nucleophilic displacement of activated nitro groups is of minor industrial significance but has considerable synthetic potential. The nucleofugicity may rival that of the corresponding fluorine substituent [24], and the nitro precursor may be more readily available than its halogen analogue. For example, the readily available 1,3-dinitrobenzene reacts with sodium methoxide to form 3-nitroanisole or with potassium fluoride (180 °C, DMF) to form 3-fluoronitrobenzene.

The choice of nitro compounds covered here is influenced strongly by their commercial application, and a good guide to this is the registration of compounds in the 1981 European Core Inventory (ECOIN). Most nitro compounds, or their derivatives, are intermediates for colorants, agrochemicals, pharmaceuticals, or other fine chemicals with a few major volume outlets for synthetic materials and explosives.

For many compounds, CAS nomenclature conventions differ from the more important names in common usage. The latter are given here, with the CAS name and number where meaningful.

2. Nitration

The unit process of nitration can be defined simply as the irreversible introduction of one or more nitro (NO_2) groups into an aromatic nucleus by replacement of a hydrogen atom. O-Nitration to give nitrates and N-nitration to give nitramines are much far less important commercially for aromatic compounds and are not dealt with here.

Nitration, an electrophilic substitution reaction, is represented by the equation:

Introduction of the nitro group so deactivates the ring to further electrophilic substitution that dinitration rarely occurs under the conditions used for mononitration. The more vigorous conditions required for dinitration (i.e., excess, stronger acid and higher temperature) must usually be applied to isolated mononitro compounds, rather than carrying out stepwise reaction in situ.

The nitration reaction is always strongly exothermic, as exemplified by the mononitration of benzene ($\Delta H = -117$ kJ/mol) and naphthalene ($\Delta H = -209$ kJ/mol) and is probably the most potentially hazardous industrially operated

unitprocess. This is due fundamentally to the heat generated, which can trigger the power of nitric acid to degrade organic materials exothermically to gaseous products with explosive violence [19]. Nitroaryl compounds, especially those with more than one nitro group, are potentially hazardous due to their very high oxygen contents. Some polynitro compounds (e.g., trinitrotoluene and picric acid) are detonable and have a long history of use as explosives [8]. A less publicized hazard with nitroaromatic compounds is occasioned by the violent decomposition reactions that may occur on heating with alkali [19].

The nitration process may be carried out on either a batch (discontinuous) or a continuous basis. Lower tonnage requirements are met by batch reaction in reactors (nitrators) designed to accommodate a variety of products. Maximum flexibility is obtained by using the more expensive enamel-lined mild-steel reactors in place of the traditional cast iron or stainless steel. The exothermic process requires efficient cooling of the reactor by jacket, internal cooling, or both. For safety reasons, the vessel is usually limited to about 6000-L capacity and is fitted with an efficient agitator.

Continuous reaction for large-tonnage intermediates (e.g., nitrobenzene and nitrotoluenes) is attractive for reasons of safety as well as the obvious economies of a dedicated unit. Whether continuous operation is achieved by a continuous mixing device or by a cascade of small agitated reactors, the material inventory is much lower than for batch reactors so the reaction temperature is easier to control. The continuous reactor requires closely defined operating parameters and management.

Typical nitroaromatic production is based on high-yield processes, with more than 80 % of the total cost being represented by the raw materials. This means that only a small proportion of the cost is available for operational savings. Two major areas that have yielded improvements are (1) the sulfuric acid recycle that has been an integral requirement of all efficient nitration processes and (2) isomer control and separation. Both these points are highlighted in more detail, together with information on plant design, in the descriptions of processes for individual products.

2.1. Nitrating Agents

For reasons of practicability and economics, industrial-scale nitration is usually carried out with a mixture of nitric and sulfuric acids (mixed acid), and occasionally with aqueous nitric acid, nitric acid in acetic acid, or nitric acid in acetic anhydride. Use of alternative component acids such as perchloric acid, hydrofluoric acid, or boron trifluoride is limited to important supporting studies. These are sometimes carried out in inert organic solvents such as chlorohydrocarbons or sulfolane to give homogeneous reaction mixtures.

The strength of the nitrating agent ($X-NO_2$) decreases with decreasing electronegativity of X [25]: nitronium ion (e.g., $BF_4^-NO_2^+$) > nitracidium ion ($OH_2^+-NO_2$) > nitronium chloride ($Cl-NO_2$) > acetyl nitrate ($AcO-NO_2$) > nitric acid ($HO-NO_2$) > ethyl nitrate ($C_2H_5O-NO_2$).

The nitronium ion, NO_2^+, is considered to be the active species in all of these systems. In the most common system the overall equation

$$HNO_3 + 2\,H_2SO_4 \rightleftharpoons NO_2^+ + H_3O^+ + 2\,HSO_4^-$$

is a composite of many equilibria present in $HNO_3-H_2SO_4-H_2O$ mixtures. These must all be taken into account when considering the reactivity of the substrate and the extent of nitration required.

A typical nitrating agent for large-scale aromatic mononitration consists of 20 % nitric acid, 60 % sulfuric acid, and 20 % water; this is referred to as 20/60/20 mixed acid. An alternative definition of the same acid, used in some situations, is 15 mol % nitric acid, 30 mol % sulfuric acid, and 55 mol % water. Commonly, the liquid aromatic substrate and the nitrated product together form a separate phase from the aqueous mixed acid. Efficient agitation is therefore required to maximize contact with the organic phase and minimize resistance to mass transfer. Solid substrates are best dissolved in the sulfuric acid phase. Stronger nitric acid leads to oxidative side reactions, whereas higher temperature leads to decreased nitronium ion concentration. Much detailed developmental work is required for each individual nitration to optimize these and other variables, to maximize formation of

the required isomer, and to minimize side reactions.

Free-radical reactions (typically in the vapor phase with nitric acid or nitrogen dioxide as nitrating agent) tend not to be employed in aromatic nitration, being more appropriate for aliphatic nitration (→ Nitro Compounds, Aliphatic). However, claims have been made that a radical mechanism makes some contribution, even when ionic mechanisms clearly predominate [26].

2.2. Reaction Mechanisms

Much experimentation has been applied to aromatic nitration since the nitronium ion, NO_2^+, was confirmed as the active species by the Ingold – Hughes school in 1950 through study of Raman spectra. Temperature and degree of mixing are important parameters for all nitrating agents, but other variables often lead to inconsistent results [27, 28, 16]. In commercial nitration with HNO_3– H_2SO_4 the relative rate constants cover a wide range, with reaction times varying from several seconds for active substrates to many hours for inactive substrates. It has been argued that under the nonideal conditions of large-scale production, nitration is controlled more by mass transfer than by kinetics, and that many laboratory studies wrongly assumed that mass-transfer resistance is negligible [29]. Another early assumption that the rate of nitration parallels the equilibrium formation of the nitronium ion was also challenged because of the realization that different mechanisms may apply at differing acid strengths [30].

Figure 1. Basic mechanism of aromatic nitration

The mechanism that can accommodate all the facts available on the nitration of simple substrates (i.e., benzene and toluene, but not phenols or polyalkylbenzenes) is shown in Figure 1 [28]. The possible involvement of four rate constants and three significant reversible reactions makes the kinetics extremely complex even if the reaction is totally kinetically controlled.

The encounter complex, or encounter pair (**2**) [27], is the novel feature of this mechanism; it is a molecular complex of less specific nature than the earlier concept of an intermediate π-complex. The important point is that **2** has a kinetic role and may indeed be rate determining. Conversion of the σ-complex (**3**), sometimes called a Wheland intermediate, to the product is not rate limiting because the nitration reaction does not exhibit a primary kinetic isotope effect. Although under certain conditions formation of the nitronium ion may be rate determining, for reactive substrates in aqueous sulfuric acid the formation of **2** is predominately the rate-determining step, whereas nitration of toluene, benzene, and other less reactive aromatic compounds obeys an overall rate law, for which formation of **3** is predominately the rate-determining step [28]; that is

$$\text{rate} = k_{\text{obsd}}\,[HNO_3]\,[ArH]\,a_{H+}$$

where k_{obsd} depends on the structure of the aromatic compound.

When the ring is highly activated towards electrophilic attack, as in the case of phenol, the nitrosonium ion (NO^+), arising from a catalytic amount of nitrous acid, comes into play, with formation of an intermediate nitroso compound, which is oxidized by nitric acid to the nitro derivative with regeneration of nitrous acid.

Ipso-electrophilic attack at a substituent position represents another exception to the general mechanism. With di- and polyalkylbenzenes the *ipso*-nitroarenium ion (**4**) may be formed instead of **3**. Although rearrangement of **4** to the conventional Wheland intermediate does occur, it is accompanied by side reactions such as

nitrodealkylation, thus giving polyalkylbenzene nitration potentially more variable mixture products than other nitrations [31]. Increased understanding of

4

the formation of ipso-Wheland intermediates has led to their exploitation in other reactions, especially with nucleophiles [16].

3. Nitro Aromatics

3.1. Nitrobenzenes

Mono-, di-, and symmetrical trinitrobenzenes are readily available by sequential nitration of benzene. Neither *o*- and *p*-dinitrobenzene nor unsymmetrical trinitrobenzenes have any significant industrial importance.

Nitrobenzene [*98-95-3*] (**5**), oil of mirbane, $C_6H_5NO_2$, M_r 123.1, is a pale yellow liquid with an odor of bitter almonds, which is readily soluble in most organic solvents and miscible with benzene in all proportions. It is a good solvent for aluminum chloride and is therefore used as a solvent in Friedel – Crafts reactions. It is only slightly soluble in water (0.19 % at 20 °C; 0.8 % at 80 °C) and is steam volatile. Binary azeotropes of nitrobenzene are listed in Table 1. Some other physical properties of nitrobenzene are as follows:

mp	5.85 °C
mp (tech. spec.)	5.5 °C (min.)
bp	
at 101 kPa	210.9 °C
at 13 kPa	139.9 °C
at 4 kPa	108.2 °C
at 0.13 kPa	53.1 °C
$d_4^{1.5}$ (solid)	1.344
d_4^{10}	1.213
$d_4^{15.5}$ (tech. spec.)	1.208 – 1.211
d_4^{25}	1.199
Viscosity (15 °C)	2.17×10^{-2} mPa · s
Surface tension (20 °C)	43.35 mN/m
Dielectric constant	
at 20 °C	35.97
at 170 °C	18.15
Specific heat (30 °C)	1.418 J/g
Latent heat of fusion	94.1 J/g
Latent heat of vaporization	331 J/g
Flash point (closed cup)	88 °C
Autoignition temperature	482 °C
Explosive limit in air (93 °C)	1.8 vol%
Vapor density	4.1
Refractive index n^{15}	1.55457

Table 1. Nitrobenzene-containing binary azeotropes

Second component	*bp* (101 kPa), °C	Nitrobenzene, wt %
Acetamide	202.0	76
Benzotrichloride	210.7	98.5
Benzyl alcohol	204.2	38
4-Chlorophenol	219.9	92
N,*N*-Diethylaniline	210.7	97
Ethyl benzoate	210.6	81
Ethylene glycol	185.9	41
Propionamide	205.4	76

Reactions of nitrobenzene involve either electrophilic meta substitution of the aromatic ring by nitration, sulfonation, or halogenation (Fig. 2, see next page), for example, or reduction of the nitro group to yield a variety of products, as shown in Table 2. The primary reduction products are nitrosobenzene, *N*-phenylhydroxylamine, and aniline, with the other products being formed by interactions and rearrangements, as shown in Figure 3 (see next page). Very specific reduction conditions are required to obtain pure products, and intermediate stages (e.g., nitrosobenzene) are not usually isolable.

Table 2. Nitrobenzene reduction products

Reducing agent	Product
Fe, Zn, or Sn/HCl, H_2 – catalyst	aniline
Zn – H_2O	*N*-phenylhydroxylamine (rearranges with acid to 4-aminophenol)
Na_3AsO_3	azoxybenzene
Zn – NaOH	azobenzene, hydrazobenzene (rearranges with acid to benzidine)
$LiAlH_4$	azobenzene
$Na_2S_2O_3$ – Na_3PO_4	sodium phenylsulfamate ($C_6H_5NHSO_3Na$)
Electrolytic reduction	4-aminophenol

Production. The traditional batchwise nitration process, in which mixed acid (27 – 32/56 – 60/8 – 17 wt %) is added to a slight excess of benzene (to avoid nitric acid in the spent acid), with the temperature controlled at 50 – 55 °C and the

Figure 2. Key intermediates derived from nitrobenzene

Figure 3. Nitrobenzene reduction products

reaction completed by heating to 80 – 90 °C, has been replaced by continuous processes that operate under similar conditions. Both economy and safety, as summarized in Section 2.1, result from the more efficient mixing and higher reaction rates possible in smaller reactors. An 120-L continuous reactor has been reported to give the same output of nitrobenzene as a 6000-L batch reactor. The variety of reactor configurations employed is typified by a stirred cylindrical reactor operating at 50 – 100 °C. The critical reuse of spent acid is achieved by continu-

Figure 4. Production of nitrobenzene – continuous process

ous concentration and addition of fresh acid, as shown in Figure 4. This differs from the concept of batchwise reuse although, in each case, addition of fresh acid or SO_3 results in the disadvantage of an equivalent amount of spent acid for disposal.

Many of the world's current production facilities are package units based on years of design experience. For example, Meissner units, with capacities up to 12 t of nitroaromatics per hour, have built-in nitrogen blanketing for additional safety. Each output stream passes through purging steps; thus, spent acid is extracted with incoming benzene to remove both residual nitrobenzene and nitric acid, while residual waste gases are scrubbed by a mixed acid loop to meet environmental regulations [32].

An alternative development from the turbulent flow tube reactor is the pump nitration circuit of Nobel Chematur. When nitration actually takes place in the pump itself, reaction times can be less than a second due to the intensive mixing, and many consequential advantages are claimed [33, 34].

The concept of an adiabatic process that uses the heat of reaction for concentration of spent acid has been around since 1941 [35]. The American Cyanamid adiabatic process [36], jointly developed with CLR, forms the basis for one of the world's largest nitrobenzene plants, rated at 159 000 t/a. This process takes cocurrent streams of benzene (1.1 mol per mole of HNO_3) and mixed acid (6 – 8/62 – 68/24 – 32 wt %) through a vigorously agitated tubular reactor, with entry at 60 – 80 °C (below the boiling point of benzene) and exit at ca. 120 °C, so engineered that the residence time is around 4 min. The requirement for much weaker sulfuric acid makes acid recycle much more economical, especially because process heat is virtually sufficient for evaporation if this is carried out under vacuum.

Another option for eliminating the need to reconcentrate the sulfuric acid in a separate step is to carry out the nitration at higher temperature (120 – 160 °C), with excess water being distilled from the nitrator as an azeotrope with benzene. In a duplex process the benzene azeotrope resulting from a high-temperature first-stage partial reaction is used in a lower temperature second stage to complete the reaction [37]. Azeotropic nitration offers considerable energy savings, but it is not thought to be competitive with adiabatic nitration.

In all these processes the work-up streams are very similar (cf. Fig. 4). The reaction mixture passes from the nitrator to a separator or centrifuge, and aqueous spent acid is fed to the recycle loop via a concentrator or strength adjustment stage as appropriate. Crude nitrobenzene, as the top layer, is passed through a series of washer – separators in which residual acid is removed by washing first with dilute alkali and then with water. The washed product is topped in a still to remove water and benzene (recycled) and, if required, finally vacuum distilled to give pure product in ca. 96 % overall yield. The washing stages give rise to an effluent problem, and wastewater treatment is necessary, principally to remove nitrobenzene.

World capacity for nitrobenzene in 1985 was ca. 1.7×10^6 t/a, with about one-third located in Western Europe and one-third in the United States [20].

Uses. The use of nitrobenzene as a processing solvent in specific chemical reactions is minor but important. Most (95 % or more) nitrobenzene produced is converted to aniline, which has hundreds of downstream products. Lower volume, but nevertheless important, industrial outlets include electrolytic reduction to 4-aminophenol, nitration to give 1,3-dinitrobenzene (**6**), chlorination to give 3-chloronitrobenzene (**7**), sulfonation to give 3-nitrobenzenesulfonic acid (**8**), and chlorosulfonation to give 3-nitrobenzenesulfonyl chloride (**9**). The last three products are consumed mainly as their reduction products, 3-chloroaniline, metanilic acid, and 3-aminobenzenesulfonamide, respectively.

Nigrosin (C.I. Solvent Black 5) survives as the crude mixture obtained by reacting nitrobenzene with aniline and aniline hydrochloride at 200 °C in the presence of iron or copper.

Toxicity. Nitrobenzene (TLV 5 mg/m^3) is very toxic and can cause acute poisoning because itis readily absorbed via the skin or respiratory tract. The primary effects are lowering of the hemoglobin level, methemoglobinemia, cyanosis, and breathlessness. Chronic exposure can lead to spleen and liver damage, jaundice, and anemia. Ingestion of alcohol may speed up and exaggerate the effects. Working conditions must be tightly specified and controlled [22].

1,3-Dinitrobenzene [*99-65-0*] (**6**), *m*-dinitrobenzene, $C_6H_4N_2O_4$, M_r 168.1, crystallizes from ethanol as pale yellow rhombic – bipyramidal plates; the compound is steam volatile. Physical properties are listed in Table 3, together with those of the 1,2- and 1,4-isomers for comparison.

Chemical reduction of 1,3-dinitrobenzene gives 3-nitroaniline or *m*-phenylenediamine, depending on conditions. Under mild conditions, 1,3-dinitrobenzene does not react with aqueous sodium hydroxide or sodium sulfite solution, whereas the 1,2- and 1,4-isomers react to form alkali-soluble nitrophenols or nitrobenzene sulfonic acids. These reactions provide the basis for the removal of small amounts of isomeric impurities from 1,3-dinitrobenzene.

Table 3. Physical properties of the three dinitrobenzenes

Property	Isomer

Solubility in chloroform (18 °C), %	27.1	32.4	1.82

∗ After sublimation.

Production. Nitrobenzene is further nitrated with strong mixed acid (HNO_3 33 wt %, H_2SO_4 67 wt %) by controlled addition and reaction at 60 – 90 °C. After completion of the reaction and addition to water the crude oil is separated while still hot. The ortho isomer (10 %), the para isomer (2 %), and nitrophenol (2 %) byproducts are removed by treatment with an aqueous NaOH – $NaHSO_3$ mixture. The final yield is ca. 82 % of 99 % pure product (*mp* 88 – 89 °C).

Uses. Catalytic hydrogenation of 1,3-dinitrobenzene yields *m*-phenylenediamine; smaller quantities are reduced with aqueous sodium sulfide to give 3-nitroaniline (Section 5.1). The I.G. Farbenindustrie developed an interesting alternative isomer-directing process for 1,3-dichlorobenzene by passing chlorine into boiling 1,3-dinitrobenzene; a 79 % yield of distilled product was reported [1]. Historically, 1,3-dinitrobenzene has been used in the formulation of explosives, lubricants, polymerization inhibitors, and corrosion inhibitors.

Toxicity. 1,3-Dinitrobenzene and its isomers are highly toxic [8] by inhalation or skin absorption. The TLV dermal is 1 mg/m^3. Prolonged exposure to small amounts can lead to accumulation in fatty tissue, with the additional danger that ingestion of alcohol can flush out these residues to produce the same severe toxic symptoms as massive exposure. Progressive symptoms of cyanosis, headaches, and vomiting can lead to severe poisoning which is signaled by

yellowing of the hair and nails in prolonged cases.

1,3,5-Trinitrobenzene [*99-35-4*] (**10**), *s*-trinitrobenzene, $C_6H_3O_6N_3$, M_r 213.1, crystallizes as yellow dimorphic crystals from ethanol or nitric acid (*mp* 61 and 122.5 °C, respectively). 1,3,5-Trinitrobenzene is inert to further ring substitution. Reduction with sodium sulfide gives 3,5-dinitroaniline and with Fe – HCl, 1,3,5-triaminobenzene. The latter is an intermediate in the production of phloroglucinol. Reaction with potassium methoxide results in the formation of 3,5-dinitroanisole via a classical Meisenheimer complex. An important property is the formation of π-complexes with hydrocarbons and other donors, which are useful in their characterization or isolation. Although trinitrobenzene has more explosive power than trinitrotoluene (TNT), it is too expensive in comparison [8].

Production. Although 1,3-dinitrobenzene may be further nitrated with strong mixed acid, extensive (dangerous) side reactions occur and the yield of 1,3,5-trinitrobenzene is low. The preferred synthesis is by decarboxylation of 2,4,6-trinitrobenzoic acid (obtained from TNT by oxidation with chromic acid) by heating in aqueous medium.

3.2. Nitrotoluenes

All three isomeric mononitrotoluenes, 2,4-dinitrotoluene (together with mixed isomeric dinitrotoluenes), and 2,4,6-trinitrotoluene (see → Explosives) are industrially important products obtained from the sequential nitration of toluene. The main outlets for mono- and dinitrotoluenes depend on their catalytic hydrogenation to the derived amines, but minor outlets also exist for sulfonated and chlorinated derivatives. Figure 5 shows key intermediates derived from nitrotoluenes.

2-Nitrotoluene [*88-72-2*] (**11**), *o*-nitrotoluene, ONT, 1-methyl-2-nitrobenzene, $C_7H_7NO_2$, M_r 137.1, is a clear yellow liquid that crystallizes at lower temperatures to solid α- or β-forms, depending on conditions. The compound is steam distillable at 100 g of ONT per kilogram of distillate. 2-Nitrotoluene is soluble in most organic solvents but only slightly soluble in water (0.065 % at 30 °C). Some physical properties are listed in Table 4, together with those of 3- and 4-nitrotoluenes for comparison.

Table 4. Physical properties of the three nitrotoluenes

Flash point (closed cup), °C	91	102	106

Reduction of 2-nitrotoluene with (1) hydrogen or iron borings and acid gives *o*-toluidine; (2) zinc dust and ammonia in aqueous ethanol gives *o*-tolylhydroxylamine, (3) iron powder and aqueous caustic soda gives *o*-azoxy- and *o*-azotoluene; and (4) zinc dust and alcoholic sodium hydroxide yield *o*-hydrazotoluene (cf. Table 2).

Oxidation of 2-nitrotoluene with manganese dioxide in sulfuric acid gives 2-nitrobenzaldehyde [*552-89-6*] (**14**) or 2-nitrobenzoic acid [*552-16-9*] (**15**), depending on the strength of the sulfuric acid. When potassium permanganate, potassium dichromate, or nitric acid is used as oxidizing agent, only 2-nitrobenzoic acid is obtained. Treatment of 2-nitrotoluene with boiling aqueous sodium hydroxide produces anthranilic acid through the unusual combination of autoxidation and reduction. However, the yield is too low for industrial use.

Reaction of 2-nitrotoluene with diethyl oxalate gives 2-nitrophenylpyruvic acid [*5461-32-5*] (**27**), which on reductive cycliza-

Figure 5. Key intermediates derived from nitrotoluenes

tion and decarboxylation converts to indole – the model example of the Reissert indole synthesis. This is one of the many reactions of 2-nitrotoluenes with neighboring group interaction to give cyclized products [38].

27

28

Nitration of 2-nitrotoluene yields a mixture of 2,4-dinitrotoluene and 2,6-dinitrotoluene. Chlorination in the presence of iron or Friedel – Crafts catalysts yields a mixture of 4-chloro-2-nitrotoluene (**16**) and 2-chloro-6-nitrotoluene (**17**), whereas in the absence of iron, 2-nitrobenzyl chloride [*612-23-7*] (**28**) or 2-chlorotoluene is formed, depending on reaction

Table 5. Nitration products of toluene with various agents

Nitrating agent	Temperature, °C	2-Nitrotoluene, %	3-Nitrotoluene, %	4-Nitrotoluene, %	Ortho – para ratio
85 % HNO_3	−30	55.6	2.7	41.7	1.33
85 % HNO_3	60	57.5	4.0	38.5	1.49
23.8 % HNO_3, 58.7 % H_2SO_4, 17.5 % H_2O	50	62.2	4.3	33.5	1.86
5.4 % HNO_3, 71.4 % H_2SO_4, 21.5 % H_2O	60	58.2	5.5	36.2	1.61
90 % HNO_3 + aromatic sulfonic acid	50	51.0	3.6	45.4	1.12
10 % HNO_3, 90 % H_3PO_4	30	45.1	4.3	50.2	0.9

conditions. 2-Nitrotoluene reacts with formaldehyde in concentrated sulfuric acid to give dinitroditolylmethane.

Production. 2-Nitrotoluene is the dominant isomer in conventional mixed acid nitration of toluene. Table 5 shows a 60 ± 5 % ortho, 38 ± 5 % para mix at different sulfuric acid strengths, as well as the products obtained by using aromatic sulfonic acid or phosphoric acid, which contain lower ortho – para ratios. This is a desirable feature because the ratio of ca. 1.6 obtained under practical mixed acid conditions does not normally match the requirements and leads to a surplus of 2-nitrotoluene. However, the phosphoric acid alternative with the desirable ratio [39] shown in Table 5 has, apart from the problem of phosphoric acid recovery, a tendency to increase the amount of dinitrotoluene formed, which leads to an apparent reduction in the amount of ortho product. Under conditions in which dinitrotoluene formation is eliminated, one evaluation of the phosphoric acid process could only achieve a reduction in the ortho – para ratio to 1.35 [40]. Many claims for alternative processes and reaction media have been patented [17] without becoming established.

Large-scale nitration is still carried out under the usual conditions of mixed acid (17 – 32/67 – 52/ca. 16 %) at 25 – 40 °C and a nitric acid to toluene molar ratio close to one. The inherent speed of reaction (17 times faster than with benzene) makes continuous reaction with low residence times most suitable. An ortho – para ratio of 1.6 and an isolated yield of 96 % total isomers are typical in a plant similar to that described for nitrobenzene but operating at as low a temperature as possible to avoid the more readily formed byproducts. The completed nitration mix is fed to a continuous, usually centrifugal, separator while hot, and the crude isomer mix is washed with dilute alkali and water (cf. nitrobenzene production). The washed product is transferred to a still, and the water and residual toluene are topped off before fractional distillation under vacuum (96 – 97 °C, 1.6 kPa) to give fairly pure 2-nitrotoluene [8].

The 1984 capacity for mononitrotoluene (all isomers) production in the Western world was ca. 200 000 t/a [20].

Uses. 2-Nitrotoluene derivatives are used principally as colorant intermediates. For example, 2-toluidine, 2-amino-4-chlorotoluene [Fast Scarlet TR Base, by reduction of 4-chloro-2-nitrotoluene (**16**)], 2-amino-6-chlorotoluene [Fast Red KB Base, by reduction of 2-chloro-6-nitrotoluene (**17**)], and 2-toluidine-4-sulfonic acid [by reduction of 2-nitrotoluene-4-sulfonic acid (**18**)] are all diazo components of azo dyes.

A more recent outlet for 2-toluidine (which is important in consuming the normal surplus of 2-nitrotoluene) is its conversion to 2-ethyl-6-methylaniline, an agrochemical intermediate.

Reduction to *o*-hydrazotoluene followed by rearrangement to 2-tolidine has virtually been phased out based on analogy with the proven carcinogen benzidine.

3-Nitrotoluene [*99-08-1*] (**12**), *m*-nitrotoluene, 1-methyl-3-nitrobenzene, $C_7H_7NO_2$, M_r 137.1, is a yellow liquid at ambient temperature; it is soluble in most organic solvents, but only slightly soluble in water (0.05 % at 30 °C). Physical properties are listed in Table 4.

Reduction of 3-nitrotoluene with hydrogen or strong reducing agents produces 3-toluidine, but treatment with Zn – H_2O or Zn – EtOH – KOH yields *m*-tolylhydroxylamine and *m*-azotoluene, respectively. Oxidation with chromic acid gives 3-nitrobenzoic acid [*121-92-6*]. Further nitration leads to a mixture of 2,3-, 2,5-, and 3,4-dinitrotoluenes (Table 6, see next page).

Production. The middle "meta fraction" distilled from the mononitrotoluene isomer mix after 2-nitrotoluene has been removed is predom-

inantly 3-nitrotoluene, but with a large 4-nitrotoluene content. This is accumulated to form the basis for more rigorous fractional distillation to give technical quality 3-nitrotoluene.

Table 6. Dinitrotoluene isomeric mixtures obtained by nitration

Starting material	Dinitrotoluene, wt %					*cp* ∗, °C
	2,3-	2,4-	2,5-	2,6-	3,4-	
Toluene	1.3	78	0.5	18	2.4	55 – 57
2-Nitrotoluene		67		33	< 0.5	50 – 51
3-Nitrotoluene	25		20		55	
4-Nitrotoluene		99				69

∗ Crystallization point of the isomeric mixture.

Uses. Catalytic hydrogenation or reduction with iron converts 3-nitrotoluene to *m*-toluidine, which provides important coupling components for azo dyes, usually after N-alkylation.

4-Nitrotoluene [*99-99-0*] (**13**), *p*-nitrotoluene, PNT, 4-nitro-1-methylbenzene, $C_7H_7NO_2$, M_r 137.1, forms colorless to light yellow rhombic – bipyramidal crystals, which are soluble in most organic solvents but only slightly soluble in water (0.044 % at 30 °C). Physical properties are listed in Table 4.

Reduction of 4-nitrotoluene with hydrogen, iron, and acid, or electrolytically in aqueous hydrochloric acid produces *p*-toluidine. Treatment with zinc dust in hot aqueous – alcoholic calcium chloride gives *p*-tolylhydroxylamine. Oxidation with chromic oxide in acetic acid produces 4-nitrobenzaldehyde [*555-16-8*]. Electrolytic oxidation in the presence of manganese salts or treatment with other strong oxidizing agents yields 4-nitrobenzoic acid, whereas controlled electrolytic oxidation in acetic acid – sulfuric acid results in 4-nitrobenzyl alcohol (**22**). Air oxidation (MeOH – KOH medium) leads to 4,4′-dinitrodibenzyl and 4,4′-dinitrostilbene.

Chlorination in the presence of Friedel – Crafts catalysts gives 2-chloro-4-nitrotoluene (**23**), whereas without catalyst 4-nitrobenzyl chloride (**24**) is produced. Further nitration or sulfonation of 4-nitrotoluene gives highly selective 2-substitution.

Production. After distillation of the meta fraction from the isomer mixture, the still residues are cooled in a crystallizer to separate technical quality 4-nitrotoluene. Further distillation of nitrotoluene residues and fractions should be implemented with great care because this has been reported to cause explosions. Holding residues at 150 – 200 °C results in an undefined "aging" process that can lead to unpredictable evolution of heat, especially if air is introduced [41].

Uses. 4-Nitrotoluene derivatives are used principally as intermediates for colorants and related products; for example, *p*-toluidine, 4-nitrobenzoic acid [*62-23-7*] (by oxidation of 4-nitrotoluene with 15 % HNO_3 at 175 °C), 4-amino-2-chlorotoluene (by reduction of 2-chloro-4-nitrotoluene), and 4-nitrotoluene-2-sulfonic acid (**25**), which is of great importance in forming stilbene intermediates for fluorescent whitening agents (see Section 6.2).

2,4-Dinitrotoluene [*121-14-2*] (**19**), DNT, 2,4-dinitro-1-methylbenzene, $C_7H_6N_2O_4$, M_r 182.1, *mp* 71 °C, *b p* 300 °C (decomp., 101 kPa), d_4^{15} 1.521, d_4^{71} 1.321, vapor density 6.27, forms yellow needles from ethanol or carbon disulfide, which are moderately soluble in most organic solvents but only sparingly soluble in water (0.03 % at 22 °C).

Reduction of 2,4-dinitrotoluene with iron – acid or H_2 – catalyst gives 2,4-diaminotoluene smoothly. Selective reduction of either nitro group may be achieved under carefully controlled conditions by using the stoichiometric amount of hydrogen with a platinum black catalyst to obtain 4-amino-2-nitrotoluene [*119-32-4*], or an equimolar quantity of tin(II) chloride in alcoholic hydrochloric acid to obtain the isomeric 2-amino-4-nitrotoluene [*99-55-8*].

Oxidation of 2,4-dinitrotoluene with aqueous nitric acid or potassium permanganate yields 2,4-dinitrobenzoic acid [*610-30-0*].

Production. 4-Nitrotoluene is nitrated with mixed acid (containing equimolar HNO_3) under controlled conditions and continuous operation to give a 96 % yield of 2,4-dinitrotoluene. In Meissner units, for tighter control of the whole process, cocurrent flow is used in each step to separate mono- and dinitration, but countercurrent flow is used between them to prevent under- or overnitration; this is also done in one-step nitration plants [32]. After nitration, if separation of the resulting emulsion is difficult, the introduction of pure product can give surprisingly rapid separation [42].

Alternative processes yield mixed isomer products. When toluene is nitrated directly under similar conditions with 2.1 equivalents of nitric acid, the product is a ca. 80 : 20 mixture of 2,4-dinitrotoluene and 2,6-dinitrotoluene [*606-20-2*]. Nitration of 2-nitrotoluene, which is sometimes present in surplus, gives a ca. 67 : 33 mixture of 2,4- and 2,6-dinitrotoluene (Table 6).

Uses. Most of the 2,4-dinitrotoluene produced is hydrogenated (nickel catalyst) to 2,4-diaminotoluene (*m*-tolylenediamine) [*95-80-7*] for conversion to toluene diisocyanate (TDI), which is a component of a polyurethane. A much smaller amount is used in explosives and for further nitration to TNT (**20**).

Crude mixtures of 2,4- and 2,6-dinitrotoluene are also used to produce mixed diamines (80 : 20 or 67 : 33, depending on the nitration process used), which in turn are converted to mixed isocyanates for polyurethane production, the use of isomer mixtures being considerably cheaper.

Toxicity of Nitrotoluenes. The toxic effects of mononitrotoluenes are similar to those described for nitrobenzene. Generally, the toxicity of alkylnitrobenzenes decreases with increasing number of alkyl groups and increases with increasing number of nitro groups. Mononitrotoluenes (TLV 30 mg/m^3) are methemoglobin formers and may be absorbed through the skin or the respiratory tract. Dinitrotoluenes (TLV 1.5 mg/m^3) and TNT (TLV 1.3 mg/m^3) are progressively more potent.

3.3. Nitroxylenes

All three xylenes can be nitrated readily, with *o*- and *m*-xylene giving mixtures of products. Even under simple conditions with mixed acid, isomer ratios can be changed significantly by varying the reaction conditions.

All five important mononitroxylenes are pale yellow oils or low-melting solids, $C_8H_9NO_2$, M_r 151.17, which are soluble in most organic solvents but only slightly soluble in water. Some physical properties are listed in Table 7.

The nitroxylenes (**29**–**33**) are all readily reduced to the corresponding aminoxylenes (xylidines). Oxidation can result in conversion of one or both of the methyl groups to a carboxylic acid group, depending on the reagent and reaction conditions. For example, **30** with aqueous nitric acid yields 2-methyl-4-nitrobenzoic acid and **31** with potassium permanganate gives 2-nitroisophthalic acid, whereas **32** results in a mixture of 4-nitroisophthalic acid and 3-methyl-4-nitrobenzoic acid under similar conditions. Further nitration of nitroxylenes in mixed acid at 35 – 50 °C with a slight excess of nitric acid gives high yields of dinitroxylenes.

Production. Batchwise nitration of *p*-xylene in mixed acid at 25 – 35 °C with a slight excess of nitric acid gives yields of 85 – 95 %. Conven-

Table 7. Physical properties of nitroxylenes

Compound	CAS registry number	*mp*, °C	*bp* (101 kPa), °C	ϱ, g/cm^3
1,2-Dimethyl-3-nitrobenzene (**29**)	[*83-41-0*]	15	246	1.1402
1,2-Dimethyl-4-nitrobenzene (**30**)	[*99-51-4*]	28 – 30	258	1.139
1,3-Dimethyl-2-nitrobenzene (**31**)	[*81-20-9*]	15	222	1.112
1,3-Dimethyl-4-nitrobenzene (**32**)	[*89-87-2*]	9	244	1.126
1,4-Dimethyl-2-nitrobenzene (**33**)	[*89-58-7*]	25	240	1.132

tional separation and workup lead to fairly pure 1,4-dimethyl-2-nitrobenzene (**33**). The mixture of **31** and **32** obtained from *m*-xylene is distilled to remove **31** and leave the main product 1,3-dimethyl-4-nitrobenzene (**32**). The mixture of **29** and **30** obtained from *o*-xylene is much more difficult to separate because the ratio is nearly 1 : 1 and their boiling points are closer. Initial fractionation by vacuum distillation is followed by a sweating process (dependent on melting point differences) to complete the purification [1].

Uses. The sole outlet for nitroxylenes is via their reduction to the corresponding xylidines. 3,4-Dimethylaniline [*95-64-7*] (3,4-xylidine, **34**), and 2,6-dimethylaniline [*87-62-7*] (2,6-xylidine, **35**) are starting materials for the production of riboflavin and agrochemicals, respectively. Other isomers are used as colorant intermediates; the most important of these are 2,4-dimethylaniline [*95-68-1*] (2,4-xylidine, **36**), used as a diazo component (e.g., in C.I. Solvent Orange 7 and C.I. Acid Red 26) and 2,5-dimethylaniline [*95-78-3*] (2,5-xylidine, **37**) used as a coupling component (e.g., in Dispersol Orange 7 and C.I. Solvent Red 26). Conveniently, mixed xylidines can be used for some colorants.

34

35

36

37

3.4. Nitronaphthalenes

Under moderate conditions, naphthalene is nitrated to give 95 % 1-nitronaphthalene (**38**) and 5 % 2-nitronaphthalene (**39**). FIERZ – DAVID [43] obtained this ratio, together with traces of dinitronaphthalene and dinitronaphthol, under a variety of conditions: (1) 20 % nitric acid at 95 – 98 °C, (2) 95 % nitric acid in acetic acid and acetic anhydride at 50 – 70 °C, and (3) HNO_3 – H_2SO_4 at 60 °C. The last conditions form the basis of large-scale production. Mixed acid nitration at higher temperature (80 – 100 °C) results in a mixture of 1,5-dinitronaphthalene (**40**) and 1,8-dinitronaphthalene (**41**) in ca. 2 : 3 ratio. This demonstrates deactivation of the ring containing the first-entering group, with the peri position then being favored in the second ring. Unlike the sulfonic acid substituent, the nitro group does not undergo migration in the naphthalene ring, and isomer ratios are therefore more constant and controllable.

38

39

40

41

All ten dinitronaphthalene isomers and many trinitro and tetranitro derivatives have been described in the literature, but only the commercially important 1,5- and 1,8-isomers are described here, together with 1- and 2-nitronaphthalenes.

Nitration of naphthalene mono- and disulfonic acids, leading to an important series of aminonaphthalenesulfonic acids, is usually performed with the appropriately formed sulfonation mass (→ Naphthalene Derivatives).

1-Nitronaphthalene [*86-57-7*] (**38**), α-nitronaphthalene, $C_{10}H_7NO_2$, M_r 173.17, *mp* 52 (metastable) – 61 °C, *bp* 304 °C (101 kPa), forms pale yellow, odorless needles that sublime at 30 – 50 °C (1.33 Pa). It is soluble in ethanol, chloroform, or ether, but insoluble in water.

Halogenation of 1-nitronaphthalene occurs in the 5- and 8-positions, and sulfonation results in 5-nitronaphthalene-1-sulfonic acid, although the latter is produced on a large scale by nitration of naphthalene-1-sulfonic acid. When chlorine gas is passed into molten 1-nitronaphthalene, the nitro group is replaced, and a mixture of chloronaphthalenes is formed.

Hydrogenation or iron reduction results in 1-aminonaphthalene; intermediate azoxy, azo, and hydrazo stages can be obtained by reduction with Zn – NaOH in alcohol. Controlled re-

duction with aqueous ammonium sulfide under mild conditions yields 1-naphthylhydroxylamine. Oxidation with air in aqueous $Ca(OH)_2$–KOH at 140 °C produces 1-hydroxy-4-nitronaphthalene. Reaction with NH_2OH – NaOEt yields 2-amino-4-nitronaphthalene.

Production. Naphthalene is charged to sulfuric acid alternately with mixed acid at 40 – 50 °C over 8 h, with the final temperature being 55 °C. The acid strength used allows the molten product to be separated as an oil and washed. Continuous operation at 50 – 60 °C with mixed acid (33/48/19) gives a comparable product. The crude reaction product is obtained in 90 – 95 % yield and is purified by vacuum distillation.

Uses. Virtually all of the 1-nitronaphthalene produced is catalytically reduced to 1-naphthylamine (→ Naphthalene Derivatives). Historically, ithas also been used as a debloming agent for petroleum and oils and as a component in the formulation of explosives.

Toxicology [22]. Vapors of 1-nitronaphthalene are poisonous and lacrimatory, being skin, eye, and mucous membrane irritants.

2-Nitronaphthalene [*581-89-5*] (**39**), β-nitronaphthalene, $C_{10}H_7NO_2$, M_r 173.17, *mp* 79 °C, *bp* 312 °C (97.4 kPa), *bp* 165 °C (2 kPa), does not sublime and is volatile in steam, in contrast to 1-nitronaphthalene. It is soluble in ethanol, ether, or chloroform, but insoluble in water.

Halogenation and sulfonation take place mainly in the 5-position, and further nitration gives a mixture of 1,6- and 1,7-dinitro- and 1,3,8-trinitronaphthalenes.

Preparation is carried out by indirect methods, for example, a nitro-Sandmeyer reaction with 2-naphthylamine.

Toxicology. 2-Nitronaphthalene is moderately toxic by ingestion and intraperitoneal routes; it is also a skin and lung irritant. 2-Nitronaphthalene is treated as a human carcinogen because it is thought to be metabolized to 2-aminonaphthalene in the human body. This is most relevant at the purification stage in the production of 1-nitronaphthalene.

1,5-Dinitronaphthalene [*605-71-0*] (**40**), $C_{10}H_6N_2O_4$, M_r 218.17, *mp* 219 °C, forms colorless needles from benzene, acetic acid, or acetone; the compound is potentially explosive [19, 22].

Reduction with iron – acid or hydrogen – catalyst yields 1,5-naphthalenediamine, but Zn – NH_4Cl in ethanol produces 5,5′-dinitro-1,1′-azoxynaphthalene, and reduction with ammonium sulfide gives 5-nitro-1-aminonaphthalene. Nitration of **40** produces 1,4,5-trinitronaphthalene, whereas sulfonation with 20 % oleum results in 1,5-dinitronaphthalene-3-sulfonic acid. Vigorous oxidation with nitric acid at 150 °C gives a mixture of 3,5-dinitrobenzoic acid, 3-nitrophthalic acid, and picric acid.

Production. Naphthalene is added slowly to mixed acid (22/58/20) at 40 °C, and the temperature is raised to 80 °C over 4 h to give a mixture of 1,5- and 1,8-dinitronaphthalenes. The isomers are separated by fractional crystallization (e.g., from ethylene dichloride) or, preferably, by solvent extraction [44]. The 1,5-isomer can be extracted with toluene, leaving 99 % pure 1,8-dinitronaphthalene. After evaporation of the toluene, the residue is extracted with a strongly polar solvent (e.g., sulfolane) to leave 99 % pure 1,5-isomer.

World production of dinitronaphthalenes occurs mainly in the Federal Republic of Germany and Japan, with the capacity of the latter reported to be 1200 t/a.

Uses. 1,5-Dinitronaphthalene is an intermediate in the production of naphthazarin (5,8-dihydroxy-1,4-naphthoquinone) and 1,5-naphthalenediamine, which is mainly converted to naphthalene 1,5-diisocyanate. As a sensitizing agent for ammonium nitrate explosives the use of mixed isomers is adequate.

1,8-Dinitronaphthalene [*602-38-0*] (**41**), $C_{10}H_6N_2O_4$, M_r 218.17, *mp* 172 °C, forms colorless or pale yellow plates from ethanol or chloroform; the compound is potentially explosive. It is sparingly soluble in organic solvents and insoluble in water.

Chlorination yields 1,4,5-trichloronaphthalene, and nitration gives 1,3,8-tri- and 1,3,6,8-tetranitronaphthalenes. Sulfonation with sulfuric acid yields 4,5-dinitronaphthalene-2-sulfonic acid, but treatment with oleum at 40 – 50 °C results in 4-nitroso-5-nitro-1-naphthol. Selective hydrogenation to give 8-nitro-1-aminonaphthalene can be achieved with a platinum black catalyst.

Production. 1,8-Dinitronaphthalene is produced by separation from the mixed isomers obtained on nitration of naphthalene (see above).

Uses. 1,8-Dinitronaphthalene is catalytically hydrogenated to 1,8-naphthalenediamine for use mainly as a colorant intermediate for naphthperinones. If demand for the 1,5-isomer as an isocyanate precursor increases, one outlet for the surplus 1,8-isomer would be direct conversion to sulfur dyes.

3.5. Other Nitro Aromatics

Although ethylbenzene and cumene are readily available and can be nitrated under similar conditions to toluene, their nitro derivatives very rarely supplant the nitrotoluenes as precursors. A startling technical advantage of, for example, an ethyl homologue over a toluene derivative would be required to justify the establishment of large-scale nitro isomer separation. Table 8 records the isomer trends on nitration of higher alkylbenzenes under comparable conditions. The ortho – para ratio decreases incrementally due to steric hindrance [45].

Table 8. Isomer ratios obtained from nitration of monoalkylbenzenes with mixed acid

Starting	Nitro isomers, wt %			Ortho – para
material	Ortho	Meta	Para	ratio
Toluene	58.5	4.5	37	1.58
Ethylbenzene	45.0	6.5	48.5	0.93
Cumene	30.0	7.7	62.3	0.48
tert-Butylbenzene	15.8	11.5	72.7	0.22

Nitration of polyalkylbenzenes (e.g., mesitylene and durene) requires extra care because of oxidation and other side reactions that can easily result from nitrosation and ipso substitution. Trinitromesitylene is prepared readily from mesitylene and mixed acid, and has been used as an explosive [8]. Two nitro derivatives of mesitylene are, however, of more recent importance as intermediates for colorants. Mesidine [*88-05-1*] (2,4,6-trimethylaniline, **42**) is produced by reduction of 1,3,5-trimethyl-2-nitrobenzene [*603-71-4*], which is obtained by nitration of mesitylene under special conditions, e.g., low temperature in the presence of acetonitrile and sulfamic acid [46]. 3,5-Diamino-2,4,6-trimethyl-benzenesulfonic acid [*32432-55-6*] (**43**) is produced by dinitration of the reaction mixture from the monosulfonation of mesitylene followed by reduction of the dinitro mesitylenesulfonic acid.

42

43

4. Nitrohalo Aromatics

4.1. Chloronitrobenzenes

The three isomeric monochloronitrobenzenes and 2,4-dinitrochlorobenzene are industrially important; all except 3-chloronitrobenzene are obtained by nitration of chlorobenzene. The primary outlets for chloronitrobenzenes depend on nucleophilic reactions (e.g., amination and alkoxylation), reduction of the nitro group, and electrophilic ring substitution (e.g., sulfonation). This makes them highly versatile primary intermediates with a wide range of derived products, as shown in Figures 6 and 7, for use in the production of colorants and other effect chemicals [47].

2-Chloronitrobenzene [*88-73-3*] (**44**), OCNB, 2-nitrochlorobenzene, $C_6H_4ClNO_2$, M_r 157.56, crystallizes as light yellow monoclinic needles. The compound is very soluble in ether, benzene, or hot ethanol, but insoluble in water. Physical properties are listed in Table 9, together with those of 3- and 4-chloronitrobenzene for comparison.

Table 9. Physical properties of the three monochloronitrobenzenes

Property	Isomer		
	Ortho	Meta	Para
mp, °C	33	46 (stable) 24 (labile)	83
bp, °C (kPa)	245.5 (100) 119 (1.1)	235.5 (101)	242 (101) 113 (1.1)
Density, g/cm^3 (°C)	1.368 (22) 1.305 (80)	1.534 (20) 1.310 (80)	1.520 (22) 1.303 (85)
Dielectric constant (°C)	37.7 (50)	20.9 (50)	12.7 (83.5)
Flash point (closed cup), °C	127	127	

Figure 6. Key intermediates derived from 2-chloronitrobenzene

Reduction of the nitro group with Fe – HCl gives 2-chloroaniline, with alternative reducing agents giving intermediate reduction products analogously to nitrobenzene (Fig. 3). The chlorine atom is readily replaced by nucleophilic attack to give hydroxy, alkoxy, and amino derivatives (Fig. 6). Electrophilic ring substitution (e.g., by halogenation, nitration, or sulfonation) takes place mainly in the position meta to the nitro group.

Production. Nitration of chlorobenzene with mixed acid (30/56/14) typically gives an isomer mix in 98 % yield consisting of 34 – 36 % 2- chloronitrobenzene, 63 – 65 % 4- chloronitrobenzene, and only ca. 1 % 3- chloronitrobenzene. The ortho – para ratio of about 0.55 is in sharp contrast to the 1.6 obtained with nitrotoluene isomers (Section 3.2). As with the nitration of toluene, much work has been done on isomer control so that the producer might have some flexibility towards the balance of isomer demand. Although no major change in ratio has been achieved, the situation is better for nitrochlorobenzene than nitrotoluenes, because the favored isomer is in much greater demand. In further contrast to the nitration of toluene, the nitration of chlorobenzene in the presence of phosphoric acid decreases the proportion of 4- chloronitrobenzene [40],and the use of phosphoric acid in the presence of a transition-metal catalyst is said to increase the ortho – para ratio to ca. 0.8 [48].

Figure 7. Key intermediates derived from 4-chloronitrobenzene

Even though the rate of nitration of chlorobenzene is an order of magnitude slower than that of benzene, comparable temperatures (40 – 70 °C) are adequate, and the techniques and equipment are very similar to those described for benzene (Section 3.1). In Meissner units the slower reaction rate is compensated by placing additional reactors in series, thereby facilitating flexible operation of this plant type as a basis for multipurpose installations [32].

The mixed product output stream is the same whether produced by a batch or continuous process, and the isomers are separated by a combination of fractional crystallization and distillation. For a simple first separation the isomer mixture is held at a temperature slightly above its crystallization point (15 °C), whereby much

of the 4-chloronitrobenzene crystallizes and can be separated. Fractional distillation gives a para-rich distillate containing all the meta isomer and an ortho-rich still residue. Each of these is crystallized, separated, and the liquid component is refractionated to gradually accumulate high-purity ortho and para products, together with intermediate fractions for continual recycle.

Estimated 1985 product figures for 2- and 4-chloronitrobenzene are for the Federal Republic of Germany 60 000 t/a, the United States 40 000 t/a, and Japan 30 000 t/a.

Uses. 2-Chloronitrobenzene derivatives (Fig. 6) find many outlets in the synthesis of colorants and effect chemicals. Reduction with iron produces 2-chloroaniline [*95-51-2*] (**45**, Fast Yellow G Base), and electrolytic reduction followed by rearrangement of the resulting hydrazo derivative leads to 3,3′-dichlorobenzidine [*91-94-1*], both of which are important diazo components. In the alternative, more economical hydrogenation process, a modified catalyst is required to inhibit dechlorination as a side reaction. Typically, a platinum on carbon catalyst, together with a small quantity of an inorganic acid acceptor such as magnesium oxide, is used; however, up to 2 % aniline may still be formed. The alternative use of morpholine as a dechlorination suppressor, rather than just an acid acceptor, is recommended for 2- and 4-chloronitrobenzene, this reduces the extent of dechlorination to 0.5 % [49]. The use of modified catalyst systems based on platinum, rather than the conventional nickel catalyst used in the production of most aniline derivatives, is essential for hydrogenation of all nitrohalo aromatics.

Treatment of 2-chloronitrobenzene with aqueous sodium hydroxide at 130 °C produces 2-nitrophenol (**46**; cf. Chap. 7), whereas treatment with MeOH – NaOH gives 2-nitroanisole (**47**) or with EtOH – NaOH 2-nitrophenetole (Chap. 7), all of which are used as precursors of the derived amines and many other products. Treatment with aqueous ammonia at 175 °C under pressure yields 2-nitroaniline (**48**; cf. Chap. 5). Sulfonation yields 4-chloro-3-nitrobenzenesulfonic acid (**49**), and chlorosulfonation gives the corresponding 4-chloro-3-nitrobenzenesulfonyl chloride (**50**). Reaction with sodium disulfide gives 2,2′-dinitrodiphenyl disulfide (**51**), which on oxidation with chlorine gives 2-nitrobenzenesulfonyl chloride (**52**). The three derivatives **49**, **50**, and **52** are all precursors to further series of intermediates (cf. Chaps. 6 and 7).

3-Chloronitrobenzene [*121-73-3*] (**7**), 3-nitrochlorobenzene $C_6H_4ClNO_2$, M_r 157.56, forms pale yellow prisms (from ethanol), which can exist as a stable or a labile modification in the solid state. The compound is insoluble in water, readily soluble in benzene or ether, and soluble in acetone or hot ethanol. Physical properties are listed in Table 9 together with those of 2- and 4-chloronitrobenzenes for comparison.

Reduction of the nitro group with Fe – HCl gives 3-chloroaniline, and ring substitution with electrophiles yields mixtures of products. Unlike the 2- and 4-isomers, the chlorine atom of 3-chloronitrobenzene is not activated towards nucleophilic substitution.

Production. Nitrobenzene is chlorinated at 35 – 45 °C in the presence of sublimed iron(III) chloride to give an isomer mixture containing 86 % of the desired 3-isomer. A continuous process has been described that uses a series of reactors operating at 35 – 55 °C, with a residence time of 5 h [50]. Purification is achieved by a combination of distillation and crystallization [51]. Disposal of the byproducts, 10 % 2-chloronitrobenzene and 4 % 4-chloronitrobenzene, can be achieved by feeding them to the mixed isomer stream in the chlorobenzene nitration plant. The 1 % crude 3-chloronitrobenzene from this plant may similarly be fed to the purification stream of the chlorination plant. Final purification of 3-chloronitrobenzene may be achieved chemically by caustic hydrolysis of the residual 2- and 4-chloronitrobenzenes and washing them out as nitrophenols.

Uses. Reduction of 3-chloronitrobenzene to 3-chloroaniline [*108-42-9*] (Orange GC base) is its primary outlet, with minor uses in other fields [51]. Crude 3-chloronitrobenzene can be used for exhaustive chlorination to give pentachloronitrobenzene (Section 4.2).

4-Chloronitrobenzene [*100-00-5*] (**53**), PCNB, 4-nitrochlorobenzene, $C_6H_4ClNO_2$, M_r 157.56, crystallizes as light yellow monoclinic prisms, which are insoluble in water and very soluble in toluene, ether, acetone, or hot ethanol. Physical properties are listed in Table 9 together

with those of 2- and 3- chloronitrobenzenes for comparison.

Reactions of 4- chloronitrobenzene are similar to those of 2- chloronitrobenzene: nitration gives 2,4-dinitrochlorobenzene, chlorination gives 3,4-dichloronitrobenzene, and sulfonation gives 6- chloro-3-nitrobenzenesulfonic acid.

Production. Nitration of chlorobenzene and separation of the isomers have already been described for 2- chloronitrobenzene.

Uses. 4-Chloronitrobenzene derivatives find important outlets in many key intermediate chains (Fig. 7). The first stages in these chains are 4- chloroaniline [*106-47-8*] (**54**), 4-nitrophenol (**55**), 4-nitroanisole (**56**) (cf. Chap. 7), 4-nitroaniline (**57**; cf. Chap. 5), 6-chloro-3-nitrobenzenesulfonic acid (**58**; cf. Chap. 6), 2,4-dinitrochlorobenzene (**59**), and 3,4-dichloronitrobenzene (**60**).

Reaction with sodium sulfide can be controlled to give 4-amino-4′-nitrodiphenyl sulfide (**64**), which after N-acetylation and oxidation with hydrogen peroxide forms **65**: subsequent reduction and hydrolysis yields 4,4′-diaminodiphenyl sulfone [*80-08-0*] (dapsone, **66**), a valuable drug in the treatment of leprosy. Dapsone is also used as an analytic reagent and can alternatively be obtained via the reaction of 4- chloronitrobenzene with 4-acetylaminobenzenesulfinic acid to give (**65**).

Condensation of 4- chloronitrobenzene with 2,4-dichlorophenol gives 2,4-dichloro-4′-nitrodiphenyl ether [*1836-75-5*] (**67**) which is used as a herbicide (nitrofen). There are many related products of this type; for example, the more recently developed preemergent herbicide Fluoronitrofor [*13738-63-1*] (**68**) – derived by reaction of 4- chloronitrobenzene with 2,4-dichloro-6-fluorophenol.

A major outlet for 4- chloronitrobenzene exploits the condensation with aniline to give 4-nitrodiphenylamine [*836-30-6*] (PNDPA, **69**), which on reductive N-alkylation gives important antioxidants for rubber, e.g., IPPD [*101-72-4*] (**70**).

1-Chloro-2,4-dinitrobenzene [*97-00-7*] (**59**), 2,4-dinitrochlorobenzene, DNCB, $C_6H_3ClN_2O_4$, M_r 202.56, *mp* 53.4 °C (α), 43 °C (β), 27 °C (γ), *bp* 315 °C (101 kPa, decomp.), d_4^{75} 1.4982, flash point (closed cup) 194 °C. The stable α-form is obtained as yellow rhombic crystals from ether; two other unstable crystal modifications are also known. The compound is soluble in benzene or ether, and insoluble in water.

Reduction of **59** with Fe – HCl gives 2,4-diaminochlorobenzene, but selective reduction is difficult because of the high reactivity of the chlorine atom toward basic reagents. Pyridine reacts readily to form a stable pyridinium salt. Nucleophilic substitution reactions are similar to those of 2- chloronitrobenzene, except that the greatly increased activity of the chlorine atom (usually several thousandfold) means that much milder reaction conditions suffice. Further substitution on the aromatic ring is difficult, although nitration under forcing conditions yields 2,4,6-trinitrochlorobenzene [*88-88-0*] (picryl chloride).

Production. Although chlorobenzene can be dinitrated directly, this results in unnecessary isomer problems. 4-Chloronitrobenzene is usually nitrated with mixed acid (35/65) at 60 °C to give the pure dinitro isomer. However, 2-chloronitrobenzene can be nitrated to produce

1-chloro-2,4-dinitrobenzene, together with ca. 10 wt % of the isomeric 2-chloro-1,3-dinitrobenzene. This may be separated for disposal, but the mixed isomers are preferably used directly if tolerated by the end product (e.g., sulfur dyes).

Uses. Industrially, the most important derivatives of 1-chloro-2,4-dinitrobenzene are obtained by nucleophilic reactions in aqueous media at moderate temperature. Ammonia gives 2,4-dinitroaniline (Chap. 5), alkali gives 2,4-dinitrophenol (Chap. 7), and methanolic sodium hydroxide gives 2,4-dinitroanisole (Chap. 7). Refluxing with hydrazine in ethanol yields 2,4-dinitrophenylhydrazine [*119-26-6*], a reagent used for the characterization of carbonyl compounds. Reaction with ammonium thiocyanate in aqueous medium at 80 °C gives dinitrophenylrhodanate, which was used as an insecticide. Reaction with substituted anilines gives 2,4-dinitrodiphenylamine derivatives that are used as yellow disperse dyes (→ Nitro and Nitroso Dyes). Reaction with pyridine gives the reactive (2,4-dinitrophenyl)pyridinium chloride [*4185-69-7*], an intermediate in the preparation of pentamethine dyes.

Nitrochlorobenzenes, especially dinitrochlorobenzene, have traditionally been used to produce sulfur dyes; for example, C.I. Sulfur Black 1 is obtained from 2,4-dinitrochlorobenzene by prolonged refluxing with sodium polysulfide liquor.

Toxicity of Nitrochlorobenzenes. The mononitrochlorobenzenes (TLV 1 mg/m^3) are considered more toxic than nitrobenzene. They are absorbed through the skin and lungs, with lowering of the hemoglobin level and its consequential effects. 2,4-Dinitrochlorobenzene is similarly toxic and is also an extreme irritant to the skin, frequently leading to skin eruptions and allergic dermatitis [22]. These allergic properties are probably due to the antigen–antibody reaction resulting from bonding with natural proteins (cf. the Sanger test with 2,4-dinitrofluorobenzene).

4.2. Dichloro- and Polychloronitrobenzenes

Both 1,2- and 1,4-dichlorobenzene are nitrated on a large scale to give important intermediates for colorants via reduction or nucleophilic substitution reactions analogous to those used for 2- and 4-chloronitrobenzene and shown in Figures 6 and 7.

60 **71** **72** **73**

1,2-Dichloro-4-nitrobenzene [*99-54-7*] (**60**), DCNB, 3,4-dichloronitrobenzene, $C_6H_3Cl_2NO_2$, M_r 192.01, crystallizes as yellow needles from ethanol. It is insoluble in water, and soluble in benzene, ether, or hot ethanol. The stable α-form has a *mp* of 43 °C; the unstable β-form is a liquid that reverts to the α-form at 15 °C, *bp* 263 °C (101.3 kPa), d_4^{75} 1.4588.

Production. Nitration of 1,2-dichlorobenzene with mixed acid at 35–60 °C results in a mixture of 3-nitro (10 %) and 4-nitro (90 %) isomers, which are separated by crystallization. A more expensive process (two stages from chlorobenzene) is based on chlorination of molten 4-chloronitrobenzene (90–100 °C) by a process similar to that used for 3-chloronitrobenzene production. Chlorination has the advantage of giving a pure product, but it cannot be used if the isomeric 1,2-dichloro-3-nitrobenzene is also required.

Uses. Iron reduction of **60** yields 3,4-dichloroaniline [*95-76-1*], an important agrochemical intermediate. Amination produces 2-chloro-4-nitroaniline, which is an important diazo component and intermediate (Section 5.3).

Reaction of 1,2-dichloro-4-nitrobenzene with potassium fluoride in an aprotic solvent gives 3-chloro-4-fluoronitrobenzene (**74**); the derived amine is used as a herbicide intermediate.

74 **75** **76**

77

1,2-Dichloro-3-nitrobenzene [*3209-22-1*] (**71**), 2,3-dichloronitrobenzene, 3-nitro-1,2-dichlorobenzene, $C_6H_3Cl_2NO_2$, M_r 192.01, *mp* 60 °C, *bp* > 230 °C (decomp.), d_4^{80} 1.449, crystallizes as yellow monoclinic needles, which are moderately soluble in most organic solvents and insoluble in water.

Production. 1,2-Dichloro-3-nitrobenzene is a byproduct of the nitration of 1,2-dichlorobenzene.

1,3-Dichloro-4-nitrobenzene [*611-06-3*] (**72**), 2,4-dichloronitrobenzene, $C_6H_3Cl_2NO_2$, M_r 192.01, *mp* 34 °C, *bp* 101 °C (0.5 kPa), d_4^{78} 1.551, crystallizes as pale yellow needles from ethanol.

Production. 1,3-Dichlorobenzene is nitrated with mixed acid, and the product is separated from the resulting isomer mixture.

Uses. 1,3-Dichloro-4-nitrobenzene is reduced to the intermediate 2,4-dichloroaniline [*554-00-7*] (**75**). Preferential amination in the ortho position can be effected to give 5-chloro-2-nitroaniline [*1635-61-6*] which is, however, much less important than the other chloronitroanilines (see Section 5.3).

1,4-Dichloro-2-nitrobenzene [*89-61-2*] (**73**), 2,5-dichloronitrobenzene, 2-nitro-1,4-dichlorobenzene, $C_6H_3Cl_2NO_2$, M_r 192.01, *mp* 56 °C, *bp* 266 °C (101 kPa), d_4^{75} 1.4390, crystallizes as pale yellow prisms or plates from ethanol. The compound is insoluble in water and soluble in benzene, ether, or hot ethanol.

Production. Nitration of 1,4-dichlorobenzene with mixed acid at 35 – 65 °C results in a 98 % yield of essentially pure 1,4-dichloro-2-nitrobenzene.

Uses. Derivatives of **73** are used mainly as colorant intermediates. Reduction yields 2,5-dichloroaniline [*95-82-9*] (Fast Scarlet GG Base, **76**), which is sulfonated to give the equally important 2,5-dichloroaniline-4-sulfonic acid [*88-50-6*] (Fast Red FR base). Amination produces 4-chloro-2-nitroaniline (Section 5.3); hydrolysis, 4-chloro-2-nitrophenol (Section 7.1); and methoxylation, 4-chloro-2-nitroanisole (Section 7.1). Condensation with phenol gives 4-chloro-2-nitrodiphenyl ether (**77**), which is reduced to 4-chloro-2-aminodiphenyl ether (Red FG Base); a series of similarly prepared aminodiphenyl ethers are used as diazo components.

Condensation with arylamines gives nitrodiphenylamines that are used as yellow to orange disperse dyes (→ Nitro and Nitroso Dyes).

1,2,4-Trichloro-5-nitrobenzene [*89-69-0*] (**78**), 1-nitro-2,4,5-trichlorobenzene, $C_6H_2Cl_3NO_2$,

78 **79** **80**

M_r 226.46, *mp* 57 °C, *bp* 288 °C (101 kPa), d_4^{80} 1.554, crystallizes as yellow prisms from ethanol.

Production. 1,2,4-Trichlorobenzene is nitrated to give mainly the 5-nitro compound, which is purified by fractional crystallization.

Uses. Reduction of **78** gives 2,4,5-trichloroaniline [*636-30-6*], and methoxylation yields 5-chloro-2,4-dimethoxynitrobenzene (**79**) [*119-21-1*]; the latter is reduced to 5-chloro-2,4-dimethoxyaniline [*97-50-7*].

Pentachloronitrobenzene [*82-68-8*] (**80**), $C_6Cl_5NO_2$, M_r 295.36, *mp* 144 °C, *bp* 328 °C (101 kPa, decomp.), d_4^{20} 1.718, forms yellow crystals, which are moderately soluble in organic solvents and insoluble in water.

Production. Pentachloronitrobenzene is produced by nitration of pentachlorobenzene.

Uses. The early use of **80** as a fungicide (terrachlor) has led to several series of nitro-containing agrochemicals. Reduction gives pentachloroaniline [*527-20-8*], which has limited application. Reaction with ethanol – potassium hydroxide yields pentachlorophenetole, exemplifying an easy route to pentachlorophenyl ethers.

Toxicity of Di- and Polychloronitrobenzenes. All di- and polychloronitrobenzenes are moderately toxic [22] and should be handled as potential eye, nose, and skin irritants.

4.3. Chloronitrotoluenes

Of the ten chloronitrotoluene isomers available, only five are of potential technical interest. Both

nitration of chlorotoluenes and chlorination of nitrotoluenes result in isomer problems, but the latter is more substituent directive.

Side-chain chlorination of nitrotoluenes is mentioned in Section 3.2, but only 4-nitrobenzyl chloride (**24**) is technically important.

16 **17** **81** **23**

4-Chloro-2-nitrotoluene [*89-59-8*] (**16**), 2-nitro-4-chloro-1-methylbenzene, $C_7H_6ClNO_2$, M_r 171.58, *mp* 38.5 °C, *bp* 240 °C (96 kPa), d_4^{80} 1.2559, crystallizes as yellow monoclinic needles.

Production. 4-Chlorotoluene is nitrated with mixed acid (39/59/2) at 25 °C to give a mixture of 2-nitro (65 %) and 3-nitro (35 %) isomers. The major component (**16**) is separated as the lower boiling fraction on vacuum distillation. 4-Chloro-3-nitrotoluene [*89-60-1*] (**81**) can be obtained, if required, from the residue by distillation and sweating.

Uses. Reduction of **16** gives 4-chloro-2-toluidine [*95-81-8*] (Fast Red KB Base, **82**). The byproduct **81** can be methoxylated and reduced to produce cresidine [*120-71-8*] (**83**), which can, however, be obtained by several alternative routes.

82 **83** **84**

85 **86**

2-Chloro-6-nitrotoluene [*83-42-1*] (**17**), 6-chloro-2-nitrotoluene, 2-nitro-6-chloro-1-methylbenzene, $C_7H_6ClNO_2$, M_r 171.58, *mp* 37.5 °C, *bp* 238 °C (101 kPa).

Production. Chlorination of 2-nitrotoluene, in a process similar to the chlorination of nitrobenzene, gives a mixture of 6-chloro (80 %) and 4-chloro (20 %) isomers. The major component **17** is separated by vacuum distillation.

Uses. Reduction of **17** gives 6-chloro-*o*-toluidine [*87-63-8*] (Fast Scarlet TR Base, **84**) which, apart from forming azo dyes, is used to produce 2,6-dichlorotoluene, by Sandmeyer reaction, for conversion to 2,6-dichlorobenzaldehyde.

2-Chloro-4-nitrotoluene [*121-86-8*] (**23**), 4-nitro-2-chloro-1-methylbenzene, $C_7H_6ClNO_2$, M_r 171.58, *mp* 68 °C, *bp* 264 °C (101 kPa), crystallizes as yellow needles from ethanol. The compound is soluble in most organic solvents, only slightly soluble in hot water, and steam volatile.

Production. Chlorination of 4-nitrotoluene at 50 °C in the presence of iron(III) chloride catalyst gives good conversion to 2-chloro-4-nitrotoluene, the most readily obtained of all the chloronitrotoluene isomers.

Uses. Reduction of **23** gives 2-chloro-4-toluidine [*95-74-9*] (**85**), which undergoes sulfonation to give 4-amino-6-chlorotoluene-3-sulfonic acid [*88-51-7*]. Further chlorination of **23** gives 2,6-dichloro-4-nitrotoluene [*7149-69-1*] (**86**) for reduction to 2,6-dichloro-*p*-toluidine [*56461-98-4*].

4-Nitrobenzyl chloride [*100-14-1*] (**24**), 1-chloromethyl-4-nitrobenzene, $C_7H_6ClNO_2$, M_r 171.58, *mp* 71 °C, forms pale yellow plates or needles from ethanol.

Production. Chlorination of 4-nitrotoluene at 190 °C without catalyst gives **24**. The alternative process of nitration of benzylchloride coproduces 2-nitrobenzyl chloride (**28**) and requires a difficult separation stage.

Uses. 4-Nitrobenzyl chloride is used as an alkylating agent (e.g., in a biosynthetic penicillin) and in the production of 4-nitrobenzyl cyanide [*555-21-5*] (**87**), which is hydrolyzed to 4-nitrophenylacetic acid [*104-03-0*] (**88**), an acylating agent.

24 **87** **88**

Toxicity of Chloronitrotoluenes. In the absence of detailed information on individual products, all chloronitrotoluenes should be assumed to have a toxicity similar to that of chloronitrobenzenes and should be handled accordingly.

4.4. Fluoronitrobenzenes and Fluoronitrotoluenes

The two most technically important classes of fluoronitrobenzenes and fluoronitrotoluenes are (1) those fluoronitrobenzenes that can be manufactured conveniently by halogen-exchange reactions, with the readily available chloronitrobenzenes and (2) nitration products from benzotrifluoride and chlorobenzotrifluorides.

Nitration of fluorobenzene with mixed acid gives a 92 : 8 mixture of 4-fluoronitrobenzene [*350-46-9*] (**89**) and 2-fluoronitrobenzene [*1493-27-2*] (**90**). However, production of these two compounds and of 2,4-dinitrofluorobenzene [*70-34-8*] (**91**) is always based on fluorine-exchange reaction of the corresponding chloro compound by treatment with potassium fluoride in a polar solvent such as dimethylformamide or dimethyl sulfoxide [52]. These compounds and their homologues form the basis for many substituted fluoro aromatics by further substitution of the nitro compounds or their derived amines. Fluoro aromatics often justify the additional costs over the corresponding chloro compounds in agrochemicals because of the lower dosage required and their greater selectivity and safety. Examples are the fungicide fluoroimide [*41205-21-4*] (**92**), derived from 4-fluoroaniline, and the herbicide flampropisopropyl [*52756-22-6*] (**93**), from 3-chloro-4-fluoroaniline (the reduction product of **74**).

89

90

91

92

93

Ring-substituted fluoronitrotoluenes have no particular advantage over the available fluoronitrobenzenes, but side-chain fluorinated toluenes (i.e., substituted benzotrifluorides) are of great importance. The I.G. Farbenindustrie produced a large range of substituted aminobenzotrifluorides as speciality fast salts that give Naphtol azo derivatives of high lightfastness. Most of these amines were derived from the corresponding nitro compounds, and some products have survived as speciality dye components. More important, the chemistry of these substituted benzotrifluorides has been exploited in the production of agrochemicals containing the trifluoromethyl group.

Benzotrifluoride is nitrated to give 3-nitrobenzotrifluoride [*98-46-4*] (**94**) in high yield, even after separation of the coproduced 6 % ortho and 3 % para isomers. Under similar conditions, 2-chlorobenzotrifluoride yields 2-chloro-5-nitrobenzotrifluoride [*777-37-7*] (**95**), and 4-chlorobenzotrifluoride yields 4-chloro-3-nitrobenzotrifluoride [*121-17-5*] (**96**). Forcing nitration of **94**, **95**, or **96** at 100 °C gives the 3,5-dinitro derivatives, with 4-chloro-3,5-dinitrobenzotrifluoride [*393-75-9*] (**97**) being the most important example.

94

95

96

97

Nitration of 3-chlorobenzotrifluoride gives a mixture of isomers from which the desired 5-chloro-2-nitrobenzotrifluoride [*118-83-2*] (**98**) is separated by crystallizing it at 5 °C and centrifuging off the unwanted isomer as an oil.

98

99

100

Iron reduction of the mononitro compounds **94**, **95**, **96**, and **98** gives a series of trifluoromethylanilines used as diazo compounds, e.g., 2- chloro-5-trifluoromethylaniline [*121-50-6*] from **96** as Fast Orange RD Base and 4- chloro-2-trifluoromethylaniline [*445-03-4*] from **98** as Scarlet VD Base. Reaction of **96** with sodium ethyl sulfinate gives the nitrosulfone (**99**), which on reduction gives 3-amino-4-ethylsulfonylbenzotrifluoride [*382-85-4*]; used as Fast Golden Orange GR Base. 3-Aminobenzotrifluoride [*98-16-8*], obtained by hydrogenation of **94**, is more important as an intermediate for drugs and crop protection chemicals than for colorants.

Reaction of **97** with dialkylamines produces a range of 2,6-dinitro-4-trifluoromethyl-*N*,*N*-dialkylanilines used as preemergent herbicides, typified by trifluralin [*1582-09-8*] (**100**).

The fluorine atom in dinitrofluorobenzenes is readily displaced, as evidenced by the use of 2,4-dinitrofluorobenzene (**91**) in the Sanger method for determination of the N-terminal amino group of a peptide chain.

5. Nitroamino Aromatics

All the isomeric mononitroanilines and many of their derivatives are industrially important. Production as colorant intermediates has made them available as starting materials for many other outlets. The most important additional substituents are nitro (i.e., dinitroanilines), chloro (i.e., chloronitroanilines), and methyl (i.e., nitrotoluidines).

The aromatic nitroamino compounds are weakly basic amines due to the strongly electron-withdrawing nature of the nitro group, especially when it is in a position ortho or para to the amino group. Widely varying p*K* values have been reported, and a comparison of their ionization constants relative to 4-nitroaniline (Table 10) is useful to indicate the extent of protonation in different strengths of sulfuric acid at different temperatures [53]. This is important when nitroanilines undergo reaction (e.g., nitration or diazotization) in sulfuric acid, although solubility must also be considered.

An alternative measure of the basicity of nitroanilines is to consider their polarity as exhibited by the main absorption maximum in a comparable series of monoazo dyes, for example, as exemplified by **101**.

Table 10. pK_a values for the ionization of primary nitroanilines in aqueous H_2SO_4

Compound	25 °C	90 °C
4-Nitroaniline	1.00	0.60
2-Nitroaniline	− 0.30	− 0.51
4-Chloro-2-nitroaniline	− 1.06	− 1.15
2,5-Dichloro-4-nitroaniline	− 1.75	− 1.76
2-Chloro-6-nitroaniline	− 2.38	− 2.35
2,6-Dichloro-4-nitroaniline	− 3.27	− 3.12
2,4-Dinitroaniline	− 4.27	− 3.81
2,6-Dinitroaniline	− 5.39	− 4.72
2-Bromo-4,6-dinitroaniline	− 6.69	− 5.81
2,4,6-Trinitroaniline	− 10.03	− 8.67

101

Table 11 shows the trend of bathochromic shift with increasing polarity [54]. These absorption maxima are not necessarily related directly to the p*K* values of the nitroanilines because the steric effects of the ortho substituents may differ in each series. Crowding due to the two chlorine substituents in example 4 results in loss of molecular planarity and broadening of the absorption band. The *o*- cyano group (examples 6 and 8) does not exert steric effects in the same way and therefore has a more powerful effect than a nitro group in the same position. 2,6-Dicyano-4-nitroaniline (example 8) is the most bathochromic nitroaniline in this series for comparison with nitro heterocyclic amines used in monoazo dyes (cf. Chap. 9).

Table 11. Substituent effect on absorption in a series of nitroaniline-based dyes (**101**)

Example	X	Y	Z	λ_{max} (in MeOH), nm
1	NO_2	H	H	425
2	H	H	NO_2	453
3	Cl	H	NO_2	475
4	Cl	Cl	NO_2	417
5	NO_2	H	NO_2	491
6	CN	H	NO_2	504
7	NO_2	NO_2	NO_2	520
8	CN	CN	NO_2	549

Nearly all the primary nitroanilines have found use as diazo components, mainly in pig-

ments or disperse dyes, and the most weakly basic of them (e.g., examples 4–8 in Table 11) require diazotization with nitrosylsulfuric acid. Isolated diazo compounds have long been known to be unstable, and often detonatable. However, not until a serious accident in 1969 during diazotization of 6-chloro-2,4-dinitroaniline with nitrosylsulfuric acid were concentrated solutions of certain diazotized nitroanilines in sulfuric acid found to be detonatable [55].

Although aniline and *C*-alkylanilines can be nitrated, this is not a viable route for production of the more important nitroanilines. However, nitrations of this type are important in studying the effects of cationic species (positive poles) on aromatic nitration. Careful analysis of the classical work claiming complete meta nitration of PhN^+Me_3 showed that 89 % of the meta isomer and 11 % of the para isomer are produced, and that the proportion of para substitution increases for PhN^+HMe_2 (22 %), PhN^+H_2Me (30 %), and PhN^+H_3 (38 %), all nitrated at 25 °C in 98 % sulfuric acid. Direct nitration of aniline is sensitive to sulfuric acid concentration, with para nitration increasing to 52 % in 89 % sulfuric acid, but this does not correlate with the calculated amount of protonated amine, so both meta and para substitution must result from nitration of the anilinium ion [56].

Nitration of *o*- and *p*-toluidines at low temperature gives desirable isomers by more controlled meta substitution than with aniline. Nitrochlorotoluenes with the required substitution pattern are less readily available than nitrochlorobenzenes or nitrodichlorobenzenes, which are used predominantly as precursors in the manufacture of nitroanilines and chloronitroanilines by nucleophilic amination of the active chlorine atom. When 3-nitroaniline configurations are required, partial reduction of the dinitro compound is an option, but difficulties arise if the compound is unsymmetrically substituted.

The primary reactions undergone by nitroamino aromatics are diazotization, reduction to the corresponding diamine, and various N-acylation reactions. As diazo components, the nitroanilines and many of their derivatives found early use as fast bases for azoic dyes. The fast base name indicates the hue derived on diazotization and coupling with Naphtol AS.

5.1. Nitroanilines

2-Nitroaniline [*88-74-4*] (**48**), *o*-nitroaniline, ONA, $C_6H_6N_2O_2$, M_r 138.13, crystallizes as orange-yellow plates from water. The compound is moderately soluble in organic solvents and sparingly soluble in water (0.13 %). Physical properties are listed in Table 12 alongside those of *m*- and *p*-nitroanilines for comparison.

Table 12. Physical properties of the three mononitroanilines

Property	Isomer		
	Ortho	Meta	Para
mp, °C	71.5	114	148
bp, °C	284 (decomp.)	307 (decomp.)	331 (decomp.)
Density (15 °C), g/cm^3	1.442	1.398	1.437
Dipole moment (in benzene), D	4.23	4.68	6.2
Flash point, °C	167		199
Refractive index (°C)	1.5362 (100)	1.595 (111)	1.5401 (160)

48 **102** **55**

Production. 2-Chloronitrobenzene (Section 4.1) is heated with excess (10 mol/mol) strong aqueous ammonia in an autoclave. The temperature is gradually increased to 180 °C over 4 h and held there for 5 h more. The pressure builds up to around 4 MPa and is released to an ammonia recycle loop before the product is isolated by filtration and washing. The reaction is extremely exothermic ($\Delta H = -168$ kJ/mol), and too rapid heating or inadequate temperature control can result in a runaway reaction. Because of this hazard, I.G. Farbenindustrie [1] developed a continuous amination unit [17] for amination of chloronitrobenzenes; the process is summarized under 4-nitroaniline.

Uses. 2-Nitroaniline is reduced with Fe–acid or H_2–catalyst to *o*-phenylenediamine [*95-54-5*]. Acetylation followed by reduction gives 2-aminoacetanilide [*555-48-6*]. 2-Nitroaniline is used as a diazo component (Fast

Orange GR Base) in azo dyes and pigments (e.g., C.I. Disperse Yellow 10 and C.I. Pigment Yellow 5) and as an intermediate for vat dyes (e.g., C.I. Vat Red 14).

3-Nitroaniline [*99-09-2*] (**102**), *m*-nitroaniline, MNA, $C_6H_6N_2O_2$, M_r 138.13, crystallizes as yellow needles from water. It is moderately soluble in organic solvents and sparingly soluble in water (0.11 %). Its physical properties are listed in Table 12.

Production. 1,3-Dinitrobenzene (Section 3.1) is added to warm water containing magnesium sulfate. An aqueous solution of sodium hydrogen sulfide (6 molar equivalents) is added gradually to the vigorously stirred emulsion, and reduction is completed by heating to 90 °C. The 3-nitroaniline produced solidifies on cooling and is separated by filtration.

Uses. Acetylation of 3-nitroaniline followed by reduction gives 3-aminoacetanilide [*102-28-3*]. Diazotization, followed by reduction of the diazosulfonate with ammonium bisulfite and subsequent hydrolysis, gives (3-nitrophenyl)hydrazine [*619-27-2*]; an intermediate in the production of pyrazolone azo coupling components. 3-Nitroaniline is used as a diazo component (Fast Orange R Base) in azo dyes (e.g., C.I. Disperse Yellow 5 and C.I. Acid Orange 18).

4-Nitroaniline [*100-01-6*] (**55**), *p*-nitroaniline, PNA, $C_6H_6N_2O_2$, M_r 138.13, crystallizes as yellow needles from water. 4-Nitroaniline is moderately soluble in organic solvents and sparingly soluble in water (0.08 %). Its physical properties are listed in Table 12.

Production. Batchwise amination of 4-chloronitrobenzene (Section 4.1) is carried out at 195 °C (4.5 MPa) in a process similar to that for 2-nitroaniline.

In the alternative continuous process [1], molten 4-chloronitrobenzene and 40 % ammonia liquor in a molar ratio of 1 : 17 are pumped at 20 MPa through a steel reaction coil held at 237 – 240 °C by oil bath heating. Inflow is controlled to give a contact time of ca. 10 min, and outflow is directed into an expansion chamber with a tangential flow of hot water to give, in quantitative yield, a suspension of product that is readily isolated and washed.

The alternative historical process based on nitration of acetanilide is not economical compared with amination, but nitration of formanilide followed by alcoholysis and recycle of ethyl formate brings the costs closer [57].

Uses. The volume outlet for 4-nitroaniline is in iron reduction or catalytic hydrogenation to produce *p*-phenylenediamine (PPD) [*106-50-3*]. This is still the major route to *p*-phenylenediamine despite more recent alternatives [21]. Reaction of 4-nitroaniline with acetic anhydride gives 4-nitroacetanilide [*104-04-1*] (**103**) which, on reduction, yields 4-aminoacetanilide [*122-80-5*], an important colorant intermediate. Chlorination (aqueous $HCl - H_2O_2$) gives 2,6-dichloro-4-nitroaniline [*99-30-9*] (**104**), a diazo component specifically for yellow-brown disperse dyes (e.g., C.I. Disperse Brown 1). Bromination (aqueous $HBr - H_2O_2$) gives 2-bromo-4-nitroaniline [*13296-94-1*] (**105**), which is occasionally used as an alternative diazo component to 2- chloro-4-nitroaniline.

Diazotization of 4-nitroaniline followed by reduction with $(NH_4)_2SO_3 - NH_4HSO_3$ and hydrolysis gives (4-nitrophenyl)hydrazine [*100-16-3*], an intermediate in the production of pyrazolone azo coupling components. Reaction of 4- chloro-1-nitrobenzene with hydrazine is not a viable alternative.

4-Nitroaniline is used as a diazo component (Fast Red GG Base) in the production of disperse monoazo dyes (e.g., C.I. Disperse Orange 25, example 2 in Table 11) and pigments (e.g., C.I. Pigment Red 1). It is also used in dyes such as C.I. Direct Black 19, where the 4-nitroaniline monoazo dye is reduced with sodium sulfide to the aminoazo compound for further diazotization and coupling. Coupling of diazotized 4-nitroaniline with 2,5-dimethoxyaniline produces Black K Base (**106**).

Phosgenation of 4-nitroaniline in aqueous medium gives *N,N′*-bis(4-nitrophenyl) urea [*587-90-6*], whereas phosgenation in toluene yields 4-nitrophenyl isocyanate [*100-28-7*] (**107**). The latter is used for the production of unsymmetrical ureas by reaction with amines. For example, with 3-picolylamine the urea [*53558-25-1*] (**108**) is formed, which has been used as a rodenticide [58]. An analogous process with guanidine hydrochloride leads to Nitroquanil [*51-58-1*] (**109**), an antimalarial drug which, although it is less active against malaria than its analogue Paludrine (derived from 4-chloroaniline), is also less toxic.

108

109

2,4-Dinitroaniline [*97-02-9*] (**110**), 2,4 DNA, $C_6H_5N_3O_4$, M_r 183.12, *mp* 188 °C, d_4^{15} 1.615, flash point 224 °C, forms yellow needles from aqueous acetic acid. The compound is sparingly soluble in ethanol and insoluble in water.

Production. 2,4-Dinitrochlorobenzene (Section 4.1) is aminated with aqueous ammonia initially at 70 °C; then the temperature is allowed to rise gradually to 120 °C to complete the reaction. Only a low-pressure autoclave is required, compared with the amination of 2- chloro- and 4- chloronitrobenzene.

110

111

112

Uses. Reduction with iron – acid gives 1,2,4-triaminobenzene [*615-71-4*] and with sodium sulfide, 3,4-diaminonitrobenzene [*99-56-9*] (**111**), an intermediate for the preparation of nitroheterocyclics. Acetylation followed by reduction gives 2,4-diaminoacetanilide [*6373-15-5*]. Bromination of a sulfuric acid solution yields 6-bromo-2,4-dinitroaniline [*1817-73-8*] (**112**).

As a diazo component, 2,4-dinitroaniline typically gives violet monoazo disperse dyes when coupled with arylamines (e.g., C.I. Disperse Violet 12, **113**). The derived 6- chloro- and 6-bromo-2,4-dinitroanilines are much more important in the production of navy disperse dyes for polyester, (e.g., C.I. Disperse Blue 79, **114**) [59].

113

114

2,6-Dinitroaniline [*606-22-4*] (**117**), 2,6 DNA, $C_6H_5N_3O_4$, M_r 183.12, *mp* 142 °C, forms yellow needles from ethanol.

Production. Chlorobenzene-4-sulfonic acid is dinitrated to give 4- chloro-3,5-dinitrobenzenesulfonic acid [*88-91-5*] (**115**), which is desulfonated by heating the diluted sulfuric acid solution from the nitration mix to give 2- chloro-1,3-dinitrobenzene [*606-21-3*] (**116**); the latter is aminated to **117**.

Uses. 2,6-Dinitroaniline and its derivatives are reported to have algicidal and heribicidal activity; for example, heating with phthalic anhydride yields *N*-(2,6-dinitrophenyl)phthalimide [*57491-99-3*] (**118**) for use as a herbicide.

2,4,6-Trinitroaniline [*489-98-5*] (**119**), picramide, $C_6H_4N_4O_6$, M_r 228.12, crystallizes as yellow prisms from aqueous acetic acid; these melt at 192 – 195 °C and explode on further heating.

Production. Picric acid (Section 7.1) is converted to 2,4,6-trinitrochlorobenzene by treatment with PCl_5, or a similar chlorinating agent; this is then aminated under mild reaction conditions.

Uses. 2,4,6-Trinitroaniline is used in explosives [8] and as a diazo component for disperse dyes; in the latter, 2,4-dinitroaniline is nitrated to give picramide, and the resulting sulfuric acid solution is diazotized in situ [60]. Dyes based on picramide are reportedly improved by introduction of the nitro group by a final nucleophilic displacement reaction [$NaNO_2$ – $Cu(OAc)_2$ – DMF] [61] on the dye derived from 6-bromo-2,4-dinitroaniline (e.g., **114**).

Toxicity of Nitroamino Aromatics. All of the readily available nitroanilines are classified as highly toxic on inhalation or skin absorption. The TLV for 4-nitroaniline is 1 ppm [22].

5.2. Nitrotoluidines

The commercially available nitrotoluidine isomers, historically important as diazo bases, are obtained by low-temperature nitration of toluidines or conventional nitration of acylated toluidines. Certain isomers can be obtained by mono reduction of dinitrotoluenes, but mixtures arise unless the molecule is symmetrical (e.g., 2,6-dinitrotoluene). Nomenclature is a problem because the old usage, which still prevails in much of industry, numbers toluidines with 1-methyl, whereas many reference books adopt a convention of 1-amino.

4-Nitro-*o*-toluidine [*99-55-8*] (**120**), 2-methyl-5-nitroaniline, $C_7H_8N_2O_2$, M_r 152.15, *mp* 107 – 109 °C, d_4^{15} 1.365, crystallizes as yellow prisms from ethanol.

Production. *o*-Toluidine is nitrated at – 10 °C by slow addition of nitric acid to a solution of the amine in 98 % sulfuric acid. On quenching the nitration mixture in water and allowing the temperature to rise, a solution is obtained from which the sulfate of the product crystallizes on cooling, leaving most of the 6-nitro-*o*-toluidine byproduct in solution.

Uses. 4-Nitro-*o*-toluidine is used as a diazo component (Fast Red RL Base) in C.I. Pigment Red 12, for example.

120

121

122

123

5-Nitro-*o*-toluidine [*99-52-5*] (**121**), 2-methyl-4-nitroaniline, $C_7H_8N_2O_2$, M_r 152.15, *mp* 132 – 133 °C, d_4^{15} 1.366, crystallizes from ethanol as yellow needles.

Production. *N*-Benzenesulfonyl-*o*-toluidine is dissolved in chlorobenzene at 40 – 50 °C, and 62 % nitric acid is added gradually to give 5-nitro-*N*-benzenesulfonyl-*o*-toluidine, which is isolated and hydrolyzed in sulfuric acid to give 5-nitro-*o*-toluidine in 80 % yield.

Uses. 5-Nitro-*o*-toluidine is used as a diazo component (Fast Scarlet G Base), for example, in C.I. Pigment Red 162 and C.I. Acid Black 28.

6-Nitro-*o*-toluidine [*603-83-8*] (**122**), 2-methyl-3-nitroaniline, $C_7H_8N_2O_2$, M_r 152.15, *mp* 92 °C, *bp* 305 °C, d_4^{15} 1.378, crystallizes from ethanol as yellow leaflets.

Production. 6-Nitro-*o*-toluidine is produced by sulfide reduction of 2,6-dinitrotoluene in a process similar to that for 3-nitroaniline (Section 5.1) or by controlled hydrogenation of 2,6-dinitrotoluene with palladium on a carbon catalyst [62].

3-Nitro-*p*-toluidine [*89-62-3*] (**123**), *m*-nitro-*p*-toluidine, MNPT, 4-methyl-2-nitroaniline, $C_7H_8N_2O_2$, M_r 152.15, *mp*

117 °C, *bp* 134 °C (0.26 kPa), d^{15} 1.31, forms orange leaflets from aqueous ethanol.

Production. *N*-Acetyl-*p*-toluidine is nitrated with mixed acid, and the quenched reaction mixture is heated and hydrolyzed to 3-nitro-*p*-toluidine.

Uses. 3-Nitro-*p*-toluidine is used as a diazo component (Red GL Base) in C.I. Pigment Yellow 1 and C.I. Pigment Red 3 (**124**), among others.

124

5.3. Halogenonitroanilines

Many halogenonitroaniline isomers exist [17] but only those obtained from the readily accessible dichloronitrobenzenes have large-scale use.

4-Chloro-2-nitroaniline [*89-63-4*] (**125**), $C_6H_5ClN_2O_2$, M_r 172.57, *mp* 116 – 117 °C, flash point 191 °C, forms orange needles from water, in which it is sparingly soluble (0.05 % at 20 °C, 0.65 % at 100 °C).

Production. 1,4-Dichloro-2-nitrobenzene (Section 4.2) is aminated at 165 °C by using a process similar to that described for 2-nitroaniline.

Uses. 4-Chloro-2-nitroaniline is used as a diazo component (Red 3GL Base) in C.I. Pigment Yellow 3 and C.I. Pigment Red 6, for example.

2-Chloro-4-nitroaniline [*121-87-9*] (**62**), $C_6H_5ClN_2O_2$, M_r 172.57, *mp* 108 °C, flash point 205 °C, crystallizes from water as yellow needles.

Production. 1,2-Dichloro-4-nitrobenzene (Section 4.2) is aminated by using a similar process to that described for 4-nitroaniline.

Uses. 2-Chloro-4-nitroaniline is used as a diazo component in disperse dyes (e.g., C.I. Disperse Red 65, **126**, example 3, Table 11) for polyester or in modified basic dyes (e.g., C.I. Basic Red 18, **127**) for acrylic fibers.

Bromination of (**62**) by treatment of a sulfuric acid solution with bromine or by treatment of a hydrobromic acid solution with hydrogen peroxide gives 2-bromo-6-chloro-4-nitroaniline [*99-29-6*] (**128**), which is used occasionally as an alternative to 2,6-dichloro-4-nitroaniline (**104**) in yellow-brown dyes for synthetic fibers.

125

62

128

126

127

Acylation of **62** with the acid chloride derived from 5-chlorosalicylic acid gives *N*-(2-chloro-4-nitrophenyl)-5-chlorosalicylanilide (niclosamid) [*50-65-7*] (**129**), which is a molluscicide and anthelminthic and typifies a series of related nitrophenylsalicylanilides used for similar outlets [63].

129

5.4. Cyanonitroanilines

The cyano group as a more bathochromic (Table 11) pseudohalogen substitutent in nitromonoazodisperse dyes has found increasing use in dyeing polyester because it also confers greater lightfastness.

2-Cyano-4-nitroaniline [*17420-30-3*] (**130**) is produced by nitration of 2-chlorobenzonitrile, separation of the required 2-chloro-5-nitrobenzonitrile [*16588-02-6*], and amination of this with ammonia.

Of the many monoazo disperse dyes derived from **130**, C.I. Disperse Red 73 (**134**, example 6 of Table 11) is typical [64]. Bromination of **130** gives 6-bromo-2-cyano-4-nitroaniline (**131**), which is used in blue dyes (e.g., C.I. Disperse Blue 183, **135**) [65]. 2-Cyano-4,6-dinitroaniline (**132**) and 2,6-dicyano-4-nitroaniline (**133**) are difficult to prepare and to diazotize. The derived bright blue dyes (e.g., **136** and **137**) are best prepared by introduction of the cyano group (cuprous cyanide in dimethylformamide) into the preformed monoazo dyes obtained from 2-bromo-4,6-dinitroaniline [66] and 6-bromo-2-cyano-4-nitroaniline [67], respectively.

6. Nitroaromatic Sulfonic Acids and Derivatives

Most of the sulfonic acids derived from nitrobenzene, nitrotoluenes, chloronitrobenzenes, and related products are reduced to yield anilinesulfonic acids, for use in the synthesis of water-soluble dyes or pigments insolubilized as lakes. Some of the derived sulfonamides and sulfones are also important intermediates for colorants and fine chemicals; they are produced from the corresponding sulfonyl chlorides. The sulfonyl chloride group is more economically introduced by direct chlorosulfonation of the nitroaromatic rather than by conversion of the sulfonic acid.

6.1. Nitrobenzenesulfonic acids and Derivatives

2-Nitrobenzenesulfonic acid [*80-82-0*] (**138**), *o*-nitrobenzenesulfonic acid, $C_6H_5NO_5S$, M_r 203.18, *mp* (anhydride) 85 °C, crystallizes as very hygroscopic pale yellow crystals that form several hydrates.

Production. 2-Chloronitrobenzene is reacted with sodium disulfide at 80 °C in aqueous ethanol to give 2,2′-dinitrodiphenyl disulfide (**51**), which is isolated and treated with chlorine in mineral acid medium in the presence of nitric acid to produce 2-nitrobenzenesulfonyl chloride (**52**) by oxidative chlorination. This is hydrolyzed in dilute alkali, and the liquor of the resulting **138** is reduced with Fe – acid or H_2 – catalyst to orthanilic acid [*88-21-1*] (**139**), an important diazo component in reactive dyes for cotton.

2-Nitrobenzenesulfonyl chloride [*1694-92-4*] (**52**), $C_6H_4ClNO_4S$, M_r 221.62, crystallizes from ether, *mp* 68 – 69 °C.

Production. 2-Nitrobenzenesulfonyl chloride is isolated as an intermediate in the production of 2-nitrobenzenesulfonic acid. When 2,2′-dinitrodiphenyl disulfide is chlorinated in an organic solvent the product is 2-nitrophenylsulfenyl chloride [*7669-54-7*] (**140**).

Uses. Reduction with zinc – acid gives 2-aminothiophenol [*137-07-5*], although this is more readily produced from aniline. The main use of **52** is via derived sulfonamides; reac-

tion with ammonia produces 2-nitrobenzenesulfonamide [*5455-59-4*] (**141**), and methylamine gives the corresponding *N*-methylsulfonamide [*23530-40-7*], both of which have been patented for use as herbicides. Reaction with *N*-ethylaniline produces a nitrosulfonamide that, on reduction, gives 2-amino-*N*-ethylbenzenesulfonanilide [*81-10-7*] (**142**), a valuable diazo component for acid wool dyes.

138

139

140

141

142

Many other sulfonamides derived from aminoheterocyclics or *o*-aminobenzoic esters can be ring- closed after reduction to give compounds with a variety of reported pharmacological properties.

3-Nitrobenzenesulfonic acid [*98-47-5*] (**8**), *m*-nitrobenzenesulfonic acid, $C_6H_5NO_5S$, M_r 203.18, crystallizes in yellow plates that are slightly deliquescent in air. Both the free acid and the sodium salt are potentially unstable to heat.

Production [1]. 3-Nitrobenzenesulfonic acid is produced by dissolving nitrobenzene in 98 % sulfuric acid and heating to 80 °C. Then 65 % oleum is added at this temperature, and the reaction is completed by heating for 9 h at 105 °C (higher temperatures are unsafe). After quenching the sulfonation mass in water, neutralizing with lime, and filtering off gypsum, the calcium salt of the product is converted to the sodium salt with sodium carbonate. After calcium carbonate has been removed by filtration, the sodium salt solution can be used directly or evaporated.

The formation of 3,3′-dinitrodiphenylsulfone [*1228-53-1*] as a byproduct is claimed to be reduced from 8 to 4 % by addition of sulfur trioxide [68].

Although benzenesulfonic acid can be nitrated to give mainly 3-nitrobenzenesulfonic acid (54 %), the process is not economical.

Uses. 3-Nitrobenzenesulfonic acid is used primarily as a mild oxidizing agent or as a precursor for colorant intermediates. In the former case it is used in processing certain anthraquinone intermediates (e.g., amination of anthraquinone-1-sulfonic acid to give 1-aminoanthraquinone) or as a dye-printing auxiliary to obtain resist effects with, for example, vat dyes. Reduction of 3-nitrobenzenesulfonic acid (usually as a liquor) to the important metanilic acid is achieved with iron or by catalytic hydrogenation. The alternative reduction with zinc and alkali or with sodium amalgam yields hydrazobenzene-3,3′-disulfonic acid, which rearranges to benzidine-2,2′-disulfonic acid [*117-61-3*] on treatment with acid.

3-Nitrobenzenesulfonyl chloride [*121-51-7*] (**9**), $C_6H_4ClNO_4S$, M_r 221.62, *mp* 64 °C, is crystallized from petroleum ether.

Production. Nitrobenzene is added to excess chlorosulfonic acid, and the temperature is raised gradually to 100 °C and held there for 6 h. After cooling, the mixture is poured into ice and water, and 3-nitrobenzenesulfonyl chloride is filtered off in 75 % yield for use as a paste, after being washed (to remove acid) with cold water.

Uses. Halide exchange gives 3-nitrobenzenesulfonyl fluoride [*349-78-0*]. Reduction with aqueous sodium sulfite yields 3-nitrobenzenesulfinic acid [*13257-95-9*] (**143**), which is readily alkylated to form sulfones. When alkylation is carried out with ethylene chlorohydrin or ethylene oxide, the product is 3-nitrophenyl-2-hydroxyethylsulfone [*41687-30-3*], which is reduced to 3-aminophenyl-2-hydroxyethylsulfone [*5246-57-1*] (**144**), a valuable intermediate in the production of dyes (e.g., C.I. Reactive Blue 19).

3-Nitrobenzenesulfonyl chloride reacts with amines forming 3-nitrobenzenesulfonamide [*121-52-8*] with ammonia, and 3-nitrobenzenesulfonanilide [*80-37-5*] (**145**) with aniline. Reduction of these nitrosulfonamides yields the corresponding amines for use as diazo components.

4-Nitrobenzenesulfonic acid [*138-42-1*] (**146**), *p*-nitrobenzenesulfonic acid, $C_6H_5NO_5S$, M_r 203.18, forms hygroscopic crystals from ethyl acetate – benzene, *mp* (anhydrous) 106 – 108 °C.

143

144

145

Production. 4-Nitrobenzenesulfonic acid is produced by hydrolysis of 4-nitrobenzenesulfonyl chloride.

Uses. 4-Nitrobenzenesulfonic acid is less important than the ortho and meta isomers because sulfanilic acid and its derivatives are readily available from aniline and acetanilide.

4-Nitrobenzenesulfonyl chloride [*98-74-8*] (**147**), $C_6H_4ClNO_4S$, M_r 221.62, *mp* 80.5 °C, crystallizes from petroleum ether as colorless needles.

Production. 4,4′-Dinitrodiphenyldisulfide [*100-32-3*] (**148**), produced by reaction of 4-chloronitrobenzene with sodium disulfide, is treated with chlorine in $HCl-HNO_3$ by a process similar to that used for 2-nitrobenzenesulfonyl chloride.

Uses. Nitrosulfonamides derived from **147** have been used as herbicides. Sulfa drugs are rarely prepared from **147** because the route via *N*-acetylsulfanilyl chloride is much more economical. However, when *N*-acylsulfonamides are required, the nitro route must be used, e.g., reduction of **149** [derived from reaction of **147** with a heterocyclic amine (RNH_2), followed by acylation with acetic anhydride] under mild conditions to give the required product.

146

147

149

148

2,4-Dinitrobenzenesulfonic acid [*89-02-1*] (**150**), $C_6H_4N_2O_7S$, M_r 248.17, crystallizes from water as colorless needles of the trihydrate (*mp* 108 °C), which dehydrate above 130 °C.

Production. 2,4-Dinitrochlorobenzene is warmed with aqueous sodium sulfite to give an 80 % yield of the sodium salt of **150** [*885-62-1*] as yellow needles after salting out. The lower reactivity of 2- and 4- chloronitrobenzene requires much higher temperature for this nucleophilic sulfitation, with too many side reactions to be practicable.

Uses. Reduction of **150** gives the colorant intermediate 1,3-diaminobenzene-4-sulfonic acid [*88-63-1*] as an alternative to the sulfonation of

150

m-phenylenediamine. The sulfonic acid group of **150** can be replaced by amino and hydroxyl groups in the same way as the chlorine atom of 2,4-dinitrochlorobenzene, and sometimes the use of a water-soluble alternative may be advantageous. Treatment of **150** with chlorosulfonic acid gives 2,4-dinitrobenzenesulfonyl chloride [*1656-44-6*] which is used as a photographic chemical together with the parent sulfonic acid.

6.2. Nitrotoluenesulfonic Acids and Derivatives

Nitrotoluenesulfonic acids have properties similar to 3-nitrobenzenesulfonic acids and are reduced to toluidinesulfonic acids, which sometimes offer advantages over anilinesulfonic acids as colorant intermediates. The methyl group introduces an additional functionality, leading to alternative derivatives, mainly via oxidation reactions.

2-Nitrotoluene-4-sulfonic acid [*97-06-3*] (**18**), 3-nitro-4-methylbenzenesulfonic acid $C_7H_7NO_5S$, M_r 217.20, crystallizes from water as pale yellow hygroscopic needles of the dihydrate (*mp* 92 °C, decomp. < 245 °C).

Production. 2-Nitrotoluene is sulfonated by heating with 25 % oleum at 80 °C for 3 h, then quenching and liming to give a neutral solution of the sodium salt of **18** [1].

Uses. The total liquor of **18** is hydrogenated in situ to give *o*-toluidine-4-sulfonic acid [*618-03-1*] (**151**). Isolated 2-nitrotoluene-4-sulfonic acid may be converted to 2-nitro-*p*-toluenesulfonyl chloride [*54090-41-4*] (**152**), but the preferred process for **152** is chlorosulfonation of 2-nitrotoluene. Reaction of **152** with dimethylamine followed by reduction gives 3-amino-4-methyl-*N,N*-dimethylbenzenesulfonamide [*6331-68-6*] for use as an azoic diazo component.

151 **152**

Heating a solution of 2-nitrotoluene-4-sulfonic acid with sodium hydroxide produces the diazo component 4-sulfoanthranilic acid [*98-43-1*], and the autoxidation can be better controlled than with 2-nitrotoluene (cf. Section 3.2) to give a viable manufacturing process.

4-Nitrotoluene-2-sulfonic acid [*121-03-9*] (**25**), 5-nitro-2-methylbenzenesulfonic acid, *p*-nitrotoluene-*o*-sulfonic acid, PNTOS, $C_7H_7NO_5S$, M_r 217.20, crystallizes from water as plates of the dihydrate (*mp* 133.5).

Production. 4-Nitrotoluene is sulfonated with 25 % oleum at 60 °C and worked up to give a solution of the sodium salt of **25**.

Uses. The most important outlets for 4-nitro-toluene-2-sulfonic acid exploit the readiness with which it forms stilbene derivatives. Selfcondensation products obtained by heating in aqueous sodium hydroxide are used as yellow water-soluble cotton dyes and consist of mixtures containing 4,4′-dinitroso-2,2′-stilbenedisulfonic acid [*58058-72-3*] (**153**), 4,4′-dinitro-2,2′-stilbenedisulfonic acid [*128-42-7*] (**154**), and 4,4′-dinitrodibenzyl-2,2′-disulfonic acid [*6268-17-3*] (**155**).

The entire class of stilbene dyes (→ Azo Dyes, Chap. 4.1.2.1.) is based on this chemistry via further reaction of the condensation products, especially **154**, with aromatic amines or, more usually, with aminoazo compounds to give cheap, water-soluble orange and brown dyes.

Manufacture of pure **154** is achieved by controlled air oxidation of **25** in the presence of a catalyst. I.G. Farbenindustrie [1] used manganese sulfate and a specially designed unit to optimize air distribution and agitation. A simpler alternative is the use of sodium hypochlorite as oxidant in a process involving the simultaneous addition of oxidant and sodium hydroxide to an aqueous solution of **25** at 75 – 80 °C [69].

153

154

155

156

Apart from its use in the production of stilbene dyes, **154** is even more important as the precursor, by Fe – HCl reduction at 100 °C, of 4,4′-diamino-2,2′-stilbenedisulfonic acid [*81-11-8*], which is the basis for 80 % of all fluorescent whitening agents (→ Optical Brighteners).

Reduction of **154** with sodium sulfide results in production of the disodium salt of 4′-nitro-4-aminostilbene-2,2′-disulfonic acid [*6634-82-8*] (**156**) for use as a diazo component; for example, in polyazo dyes for which the nitro group of **156** is reduced to an azoxy group by treatment with glucose and sodium hydroxide [70].

Hydrogenation of **25** gives *p*-toluidine-2-sulfonic acid (5-amino-2-methylbenzenesulfonic acid) [*118-88-7*], which can be used as an alternative to metanilic acid. 4-Nitrotoluene-2-sulfonyl chloride [*121-02-8*] (**157**), the acid chloride of **25**, is best obtained by chlorosulfonation of 4-nitrotoluene. Reaction of **157** with aniline followed by reduction gives 4-aminotoluene-2-sulfonanilide [*79-72-1*] (**158**) for

use as a diazo component. The sulfonamide derived from **157** is oxidized and ring closed in one step to give 6-nitrosaccharin (**159**) by treatment with $CrO_3 - H_2SO_4$ at 65 – 70 °C [71].

157

158

159

2,6-Dinitrotoluene-4-sulfonic acid [*88-90-4*] (**160**), 3,5-dinitro-4-methylbenzenesulfonic acid, $C_7H_6N_2O_7S$, M_r 262.20, crystallizes as a hydrate in the form of pale yellow crystals, which soften at 110 °C, dehydrate at 140 °C, and melt at 165 °C.

Production. 2-Nitrotoluene is sulfonated to form 2-nitrotoluene-4-sulfonic acid; the reaction mixture is diluted with 90 % sulfuric acid, and sodium nitrate is added over 6 h at 80 °C. After a further 1 h at this temperature the reaction mass is poured into water and the sodium salt of the product is salted out by addition of sodium sulfate. After being washed acid-free with brine, the yield of **160** is ca. 80 %.

160

161

Uses. Reduction of **160** with sulfide gives 2-amino-6-nitrotoluene-4-sulfonic acid (**161**), and reduction with iron – acid gives 2,6-diaminotoluene-4-sulfonic acid [*98-25-9*]. 2,6-Dinitrotoluene-4-sulfonyl chloride [*80198-19-2*] is obtained from **160** by treatment with thionyl chloride. Reaction of this sulfonyl chloride with an alkylamine followed by hydrogenation leads to a readily accessible series of symmetrical diaminotoluenesulfonamides [72].

6.3. Chloronitrobenzenesulfonic Acids and Derivatives

The commercially available chloronitrobenzenesulfonic acids are usually obtained by sulfonation or chlorosulfonation of chloronitrobenzenes or by sulfition of dichloronitrobenzenes. Although the corresponding substituted anilines can be obtained by reduction, the main outlets for this group of products are via nucleophilic displacement reactions of the chlorine substituent.

2-Chloro-5-nitrobenzenesulfonic acid [*96-73-1*] (**58**), 4-chloronitrobenzene-3-sulfonic acid, PN salt, $C_6H_4ClNO_5S$, M_r 237.62, crystallizes as the dihydrate from water (*mp* 169 °C, decomp.). The compound undergoes explosive decomposition when heated above 200 °C, and all reactions, including its production, must be undertaken with great caution.

Production. 4-Chloronitrobenzene is sulfonated with 65 % oleum at 115 °C; special precaution must be taken to control temperature [41]. Work-up is by quenching and isolation of the sodium salt after it has been salted out.

Uses. Amination of **58** gives 4-nitroaniline-2-sulfonic acid [*96-75-3*] (**162**), which is used as a diazo component or reduced to the important colorant intermediate 2,5-diaminobenzenesulfonic acid [*88-45-9*]. Chlorination of **162** in aqueous solution is a more facile route to 2,6-dichloro-4-nitroaniline (**104**) than chlorination of 4-nitroaniline.

162

163

164

Monocondensation of **58** with *p*-phenylenediamine gives 4′-amino-4-nitrodiphenylamine-2-sulfonic acid [*91-29-2*] (**163**), which can be reduced to 4,4′-diaminodiphenylamine-2-sulfonic acid [*119-70-0*], a tetrazo component in direct

cotton dyes. Monoaminodiphenylaminesulfonic acid diazo components are obtained by condensation of **58** with aniline or toluidine, followed by reduction. 2-Chloro-5-nitrobenzenesulfonyl chloride [*4533-95-3*] (**164**) may be obtained from **58** but is best prepared by direct chlorosulfonation of 4-chloronitrobenzene. Amination of **164** gives 4-nitroaniline-2-sulfonamide [*54734-85-9*].

4-Chloro-2-nitrobenzenesulfonic acid (**165**), $C_6H_4ClNO_5S$, M_r 237.62, *mp* 114–115 °C (anhydrous), forms hygroscopic crystals. The sodium salt is water soluble; the potassium salt, less so (ca. 1 % at 25 °C).

Production. 4-Chloro-2-nitrobenzenesulfonic acid is obtained by alkaline hydrolysis of 4-chloro-2-nitrobenzenesulfonyl chloride [*4533-96-4*] (**166**), which is obtained from bis(4-chloro-2-nitrophenyl) disulfide (the latter is formed from 2-nitro-1,4-dichlorobenzene) by analogy with the process for 2-nitrobenzenesulfonyl chloride. The primary outlets for **166** are amination to 4-chloro-2-nitrobenzenesulfonamide [*13852-81-8*] (**167**) and further chlorosulfonation to the disulfonyl dichloride (**168**), an intermediate for a series of 4-amino-6-chlorobenzene-1,3-disulfonamides that are useful diuretics.

165

166

167

168

4-Chloro-3-nitrobenzenesulfonic acid [*121-18-6*] (**49**), $C_6H_4ClNO_5S$, M_r 237.62, crystallizes as needles from water (decomp. > 200 °C). The potassium salt forms pale yellow crystals in water, *mp* 325 °C (decomp.). The solubility of the potassium salt in water is 2 % at 30 °C versus 19 % for the sodium salt.

Production. 2-Chloronitrobenzene can be sulfonated with 65 % oleum analogously to 4-chloronitrobenzene, but the preferred process is to sulfonate chlorobenzene at 100 °C and nitrate the sulfonation mass in situ by the addition of nitric acid or potassium nitrate at 20–30 °C. The product is isolated in 90 % yield as its sodium or potassium salt by salting out from the quenched reaction mixture after addition of lime and removal of the precipitated calcium sulfate. Purification, if required, is achieved by recrystallization of the potassium salt.

Uses. Hydrolysis of **49** gives 2-nitrophenol-4-sulfonic acid [*616-85-3*] (**169**) for reduction to the diazo component 2-aminophenol-4-sulfonic acid [*98-37-3*]. Amination yields 2-nitroaniline-4-sulfonic acid [*616-84-2*] (**170**), and iron reduction produces 2-chloroaniline-5-sulfonic acid [*98-36-2*], both of which are used as diazo components. Heating **49** with aqueous sodium sulfite results in nitrobenzene-2,5-disulfonic acid [*119-00-6*] (**171**), an intermediate for an alternative route to aniline-2,5-disulfonic acid [*98-44-2*].

169

170

171

The acid chloride of **49** is best produced by direct chlorosulfonation of 2-chloronitrobenzene. 4-Chloro-3-nitrobenzenesulfonyl chloride [*97-08-5*] (**50**) is especially important as the intermediate for 4-chloro-3-nitrobenzenesulfonamide [*97-09-6*] (**172**); the latter leads to the diazo component 2-aminophenol-4-sulfonamide [*98-32-8*]. 4-Chloro-3-nitrobenzenesulfonyl chloride is also used for the production of nitro dyes, e.g., Disperse Yellow 42 (**173**) by condensation of **50** with two equivalents of aniline (→ Nitro and Nitroso Dyes).

172

173

174

175

5-Chloro-2-nitrobenzenesulfonic acid [*54481-12-8*] (**174**), $C_6H_4ClNO_5S$, M_r 237.62, forms hygroscopic crystals of the monohydrate (*mp* 93 °C).

Production. 5,5′-Dichloro-2,2′-dinitrodiphenyldisulfide (obtained from the reaction of 2,4-dichloronitrobenzene with Na_2S_2) is oxidatively chlorinated with chlorine in $HCl-HNO_3$ to give the sulfonyl chloride, which hydrolyzes to **174**.

Uses. Reduction of **174** gives 4-chloroaniline-2-sulfonic acid, and amination results in 4-nitroaniline-3-sulfonic acid, both of minor importance as intermediates. The derived sulfonyl chloride leads to 5-chloro-2-nitrobenzenesulfonamide (**175**), an intermediate in the production of the benzothiadiazine derivative diazoxide, used as a vasodilator.

2-Chloro-3,5-dinitrobenzenesulfonic acid [*4515-26-8*] (**176**), $C_6H_3ClN_2O_7S$, M_r 282.62, crystallizes from water as needles.

Production. 4-Chloronitrobenzene is sulfonated by gradual addition of 25 % oleum at 60 °C; the temperature is raised slowly to 125 °C, and held there for 8 h. The sulfonation mixture is cooled to 70 °C, nitric acid is added over 5 h, and the reaction is completed by heating for 12 h at 70 °C followed by 4 h at 100 °C. After cooling and quenching, the sodium salt of the product is salted out by addition of sodium sulfate and isolated in 80 % yield.

176

177

178

Uses. Hydrolysis of **176** with aqueous alkali readily yields 2,4-dinitrophenol-6-sulfonic acid, which is reduced with sodium sulfide to 4-nitro-2-aminophenol-6-sulfonic acid [*96-67-3*] (**177**), a diazo component of metallizable azo dyes. Under very mild conditions, **176** is aminated to 2,4-dinitroaniline-6-sulfonic acid, and **176** reacts with sodium sulfite to give 3,5-dinitrobenzene-1,2-disulfonic acid.

As a reagent for the identification of α-amino acids ($RCHNH_2COOH$), **176** forms derivatives (**178**) that are more readily hydrolyzed in acid solution to give the parent α-amino acid than the corresponding 2,4-dinitrophenyl derivatives [73].

4-Chloro-3,5-dinitrobenzenesulfonic acid [*88-91-5*] (**115**), $C_6H_3ClN_2O_7S$, M_r 282.62, forms hygroscopic crystals in water (*mp* 293 °C).

Production. 4-Chloro-3,5-dinitrobenzenesulfonic acid is produced by a process based on the sulfonation and nitration of chlorobenzene that uses 2 mol/mol of potassium nitrate, in place of the 1 mol/mol employed in the production of 4-chloro-3-nitrobenzenesulfonic acid. The product is isolated from the quenched reaction mixture as the potassium salt, after addition of potassium chloride.

Uses. Conversion of **115** to 2,6-dinitroaniline is described in Section 5.1. More important is the use of the derived sulfonyl chloride to form the sulfonamide (**179**) (a fungicide) and the sulfone (**180**). Reaction of **179** with di-*n*-propylamine forms oryzalin [*19044-88-3*], and reaction of **180** with di-*n*-propylamine forms nitralin [*4726-14-1*], both of which are important members of the large class of substituted 2,6-dinitroaniline herbicides.

179

180

6.4. Chloronitrotoluenesulfonic Acids

6-Chloro-2-nitrotoluene-4-sulfonic acid [*68189-28-6*] (**181**), 3-chloro-4-methyl-5-nitrobenzenesulfonic acid, $C_7H_6ClNO_5S$, M_r 251.65.

Production. 6-Chloro-2-nitrotoluene is sulfonated with 20 % oleum at 60 °C with careful temperature control to avoid a runaway reaction. Work-up is by conventional processes.

Uses. Reduction of **181** gives 2-amino-6-chlorotoluene-4-sulfonic acid [*6387-27-5*], which is used as a diazo component.

181 **182**

183

6-Chloro-4-nitrotoluene-2-sulfonic acid (**182**), 3-chloro-2-methyl-5-nitrobenzenesulfonic acid, $C_7H_6ClNO_5S$, M_r 251.65, crystallizes from water as hygroscopic needles.

Production. 2-Chloro-4-nitrotoluene is sulfonated with 30 % oleum at 75 °C to produce 6-chloro-4-nitrotoluene-2-sulfonic acid.

Uses. Oxidation of **182** with sodium hypochlorite gives 6,6′-dichloro-4,4′-dinitro-2,2′-stilbene disulfonic acid (**183**), which is reduced to the corresponding diamine; the latter is used in experimental fluorescent whitening agents, analogous to those obtained from 4,4′-diamino-2,2′-stilbene disulfonic acid.

Toxicology of Nitrohydrocarbon Sulfonic Acids. As a general rule the water solubility conferred by the sulfonic acid group, as well as the hydrophilicity conferred by the sulfonamide and sulfone groups, renders this group of products less toxic than their unsulfonated parent compounds. The products are less volatile, penetrate the skin less readily, and are more readily excreted if ingested. This is demonstrated by the sodium salt of 3-nitrobenzenesulfonic acid, which has an oral LD_{50} (rat) of 11 000 mg/kg, compared to 640 mg/kg for nitrobenzene.

7. Nitrohydroxy and Alkoxy Aromatics

Phenol can be nitrated with aqueous nitric acid in the presence of nitrous acid (cf. Section 2.2) to give a mixture consisting mainly of 2- and 4-nitrophenol. Although these can be separated (the ortho isomer is steam volatile), the economics of this route compares unfavorably with hydrolysis of 2- and 4-nitrochlorobenzene. Hydrolysis is also used for 2,4-dinitrophenol. Nitrocresols are more frequently obtained by nitrosation or nitration, although mixtures of isomers often result.

Nitrophenyl ethers are also produced from reactive nitrochloro compounds by reaction with alcohols or phenols. The less common *meta*-nitrophenyl ethers are prepared by methylation of the 3-nitrophenol precursor. Nomenclature with substituted anisidines and their homologues is confusing. Common practice (used here) maintains the methoxy group at the 1-position, in line with substituted phenols, but many references use the convention of the amino group in the 1-position. Only the formula or the CAS name is unambiguous for compounds such as 4-nitro-*o*-anisidine.

The most general use of both nitrophenols and nitro ethers involves reduction to the corresponding hydroxy- and alkoxyanilines.

7.1. Nitrophenols and Derived Ethers

2-Nitrophenol [*88-75-5*] (**46**), *o*-nitrophenol, $C_6H_5NO_3$, M_r 139.11, *mp* 45 °C, *bp* 216 °C (101 kPa), forms yellow needles from ethanol. It is slightly soluble in water (1 % at 100 °C) and steam volatile (intramolecular hydrogen bonding, unlike the para isomer).

Production. 2-Chloronitrobenzene in 8.5 % sodium hydroxide solution is heated gradually (exothermic) to 170 °C in an autoclave and held there under pressure for 8 h. The resulting solution is cooled and acidified to give the product in 95 % yield.

Uses. Catalytic hydrogenation (Pd–C) of 2-nitrophenol gives 2-aminophenol [*95-55-6*], which is used as a photographic developer and, in larger amounts, as a versatile intermediate for dyes and fine chemicals. 2-Aminophenol reacts with acetic anhydride to give 2-methylbenzoxazole, which is nitrated with mixed acid to give the 6-nitro derivative for subsequent hydrolysis to 5-nitro-2-aminophenol [*121-880-0*] (**184**).

2-Nitroanisole [*91-23-6*] (**47**), 2-methoxynitrobenzene, 2-nitrophenyl methyl ether, $C_7H_7NO_3$, M_r 153.13, *mp* 10 °C, *bp* 272 °C (101 kPa), is steam volatile. The compound is sparingly soluble in water, but readily soluble in ethanol, ether, or benzene.

Production. Methanolic sodium hydroxide is added slowly to a solution of 2- chloronitrobenzene in methanol at 70 °C; the mixture is then heated gradually to 95 °C under pressure to complete the reaction. After dilution with water the product is separated as an oil, in 90 % yield, and methanol is recovered from the aqueous layer.

Uses. 2-Nitroanisole is reduced (H_2– catalyst or iron – formic acid) to *o*-anisidine [*90-04-0*] or (benzidine-type reaction) to *o*-dianisidine [*119-90-4*], both of which are important as dye intermediates. Low-temperature nitration of *o*-anisidine, either directly or by addition of *o*-anisidine nitrate to sulfuric acid, gives 4-nitro-*o*-anisidine (Fast Scarlet base) [*99-59-2*] (**185**) in good yield. Nitration of *N*-acetyl- *o*-anisidine with mixed acid at 25 °C gives mainly the 5-nitro derivative, which can be separated from the 4-nitro isomer after hydrolysis to the amine because the more weakly basic 5-nitro-*o*-anisidine (Fast Red B base) [*97-52-9*] (**186**) is precipitated first on dilution of the sulfuric acid hydrolysate. Chlorosulfonation of **47** yields 2-nitroanisole-4-sulfonyl chloride [*22117-79-9*], from which *o*-anisidine-4-sulfonamide derivatives are obtained.

2-Ethoxynitrobenzene [*610-67-3*] (**187**), 2-nitrophenyl ethyl ether, 2-nitrophenetole,$C_8H_9NO_3$, M_r 167.16, *cp* 4.5 °C, *bp* 275 °C (101 kPa), is a greenish yellow oil.

Production. 2-Chloronitrobenzene in ethanol solution is treated with ethanolic sodium or potassium hydroxide in a process similar to that for 2-nitroanisole, except that the reaction mixture is aerated to avoid reduction to the potentially explosive azoxy derivative. The nitrophenol byproduct is formed in larger amounts than with nitroanisole and requires washing with alkali or post-ethylation with ethyl chloride under pressure [1].

Uses. Hydrogenation of **187** gives *o*-phenetidine [*94-70-2*] (2-ethoxyaniline), which is nitrated to 4-nitro-*o*-phenetidine.

4-Chloro-2-nitrophenol [*89-64-5*] (**188**), $C_6H_4ClNO_3$, M_r 173.56, *mp* 87 °C, forms yellow prisms from ethanol. The compound is sparingly soluble in water and is steam volatile.

Production. 2,5-Dichloronitrobenzene is hydrolyzed with 8 % aqueous sodium hydroxide at 120 – 130 °C under pressure [1].

Uses. Reduction of **188** gives 2-amino-4-chlorophenol [*95-85-2*], and chlorination yields 2,4-dichloro-6-nitrophenol [*609-89-2*] (**189**), which is reduced to 2-amino-4,6-dichlorophenol [*527-62-8*]. These substituted aminophenols are members of a large class of diazo components used for hydroxyazo dyes, which are important for wool and polyamide when converted to their chromium complexes. For the amine derived from the methyl ether of **188**, 4- chloro-*o*-anisidine [*93-50-5*], the preferred route is methoxylation of 2,5-dichloronitrobenzene followed by reduction. 2-amino-4-chlorophenol reacts with phosgene to give 5-chlorobenzoxolinone which nitrates to the 6-nitro compound (**190**); the latter undergoes alkaline hydrolysis to 2-amino-4-chloro-5-nitrophenol.

3-Nitrophenol [*554-84-7*] (**191**), *m*-nitrophenol, $C_6H_5NO_3$, M_r 139.11, *mp* 97 °C, *bp* 194 °C, forms yellowish crystals from dilute hydrochloric acid. The compound is moderately soluble in water (1 % at 20 °C, 13 % at 90 °C).

Production. 3-Nitroaniline is diazotized in aqueous sulfuric acid and then hydrolyzed by being added gradually to boiling dilute sulfuric acid. The crude product solidifies on cooling and is filtered off in 90 % yield.

Uses. Reduction of **191** gives 3-aminophenol [*591-27-5*], and methylation to 3-nitroanisole [*555-03-3*] followed by reduction gives *m*-anisidine [*536-90-3*]. Carboxylation of 3-aminophenol gives the tuberculostatic 4-aminosalicylic acid [*65-49-6*].

4-Nitrophenol [*100-02-7*] (**55**), *p*-nitrophenol, $C_6H_5NO_3$, M_r 139.11, forms yellow needles (mixed α- and β-forms), *mp* 114 °C, *bp* 216 °C (101 kPa). The (metastable) α-form crystallizes from toluene above 63 °C, and the yellow, prismatic β-form crystallizes from toluene below 63 °C. 4-Nitrophenol is not steam volatile and is much more soluble in water (30 % at 100 °C) than the ortho isomer. Its flash point is

105 °C, and the decomposition point (explosive) of the sodium salt is 156 °C.

Production. 4-Chloronitrobenzene is hydrolyzed by a process identical to that described for 2-nitrophenol.

Uses. Reduction of **55** to 4-aminophenol [*123-30-8*] has largely been superseded by processes based on direct reduction of nitrobenzene. Reaction of sodium 4-nitrophenoxide with dialkylthiophosphoric chlorides (125 °C in chlorobenzene) gives a series of insecticides typified by parathion [*56-38-2*] (**192**; R = ethyl), which has largely been displaced by the less toxic methylparathion [*298-00-0*] (**192**; R = methyl) and related products. 4-Nitrophenol reacts with 4- chloro-3-nitrobenzotrifluoride (**96**) to form fluorodifen (**193**)–related to nitrofen (**67**), mentioned in Section 4.1; it is used as a herbicide specifically on drilled rice crops.

184

185

187

188

189

190

191

192

193

4-Nitroanisole [*100-17-4*] (**56**), 4-methoxynitrobenzene, 4-nitrophenyl methyl ether, $C_7H_7NO_3$, M_r 153.13, *mp* 54 °C, *bp* 274 °C (101 kPa), forms prisms from ethanol. 4-Nitroanisole is insoluble in water, moderately soluble in ethanol or benzene and steam volatile.

Production. 4-Chloronitrobenzene is dissolved in methanol and treated with methanolic sodium hydroxide, which is added slowly at 80 – 90 °C. After completion of reaction and neutralization, the excess methanol is removed by distillation, and after cooling, the product is filtered off in 95 % yield.

Uses. Reduction of **56** with sulfide gives *p*-anisidine [*104-94-9*]. *N*-Acetyl- *p*-anisidine is nitrated with 62 % nitric acid in chlorobenzene solution to give the 3-nitro derivative for hydrolysis to 3-nitro- *p*-anisidine (Fast Bordeaux GP base) [*96-96-8*] (**194**).

4-Ethoxynitrobenzene [*100-29-8*] (**195**), 4-nitrophenyl ethyl ether, 4-nitrophenetole, $C_8H_9NO_3$, M_r 167.16, *mp* 60 °C, *bp* 283 °C (101 kPa), crystallizes from ethanol as prisms, which are insoluble in water and moderately soluble in ethanol or ether.

Production. 4-Ethoxynitrobenzene is obtained from 4- chloronitrobenzene, by a process analogous to that described for 2-ethoxynitrobenzene.

Uses. Reduction of **195** gives *p*-phenetidine [*156-43-4*], which undergoes similar reactions to *p*-anisidine and is also the intermediate for the analgesic phenacetin (4-ethoxyacetanilide [*62-44-2*]) and the sweetener dulcin (4-ethoxyphenylurea [*150-69-6*]).

2,4-Dinitrophenol [*51-28-5*] (**63**), $C_6H_4N_2O_5$, M_r 184.11, *mp* 114 °C (decomposes explosively at higher temperature), pK_a 4.89, forms yellow needles. 2,4-Dinitrophenol is sublimable, steam volatile, sparingly soluble in water (1.3 % at 100 °C), and readily soluble in acetone, ethanol, or benzene.

Production. 2,4-Dinitrochlorobenzene is hydrolyzed by heating with 6 % aqueous sodium hydroxide at 95 – 100 °C for 4 h. The product is precipitated by addition of acid, filtered off, and washed to remove acid and also a small quantity of the more soluble 2,6-isomer. The yield is 95 %.

194

195

196

197

Uses. 2,4-Dinitrophenol is used in antiseptics, as an explosives additive, as a pest control agent, and as an intermediate for black sulfur

dyes. Sulfide reduction gives 4-nitro-2-aminophenol [*99-57-0*] (**196**).

2,4-Dinitroanisole [*119-27-7*] (**197**), 1-methoxy-2,4-dinitrobenzene, $C_7H_6N_2O_5$, M_r 198.13, *mp* 83 °C, forms yellow crystals from ethanol. 2,4-Dinitroanisole is potentially explosive on heating.

Production. 2,4-Dinitrochlorobenzene is treated with methanolic sodium hydroxide in a process similar to that described for 4-nitroanisole. 2,4-Dinitrophenetole [*610-54-8*] is similarly manufactured by using ethanol.

Uses. Catalytic hydrogenation of **197** yields 2,4-diaminoanisole [*615-05-4*], which is converted by N-acylation and N′-alkylation to azo coupling components. Sulfide reduction gives 4-nitro-*o*-anisidine (**185**) as an alternative route to nitration of *o*-anisidine, but the product from this selective reduction is less pure.

2,5-Dimethoxynitrobenzene [*89-39-4*] (**198**), 2-nitrohydroquinone dimethyl ether, 1,4-dimethoxy-2-nitrobenzene, $C_8H_9NO_4$, M_r 183.13, *mp* 72 – 73 °C, forms yellow needles from aqueous ethanol.

Production. 1,4-Dimethoxybenzene is nitrated with 34 % nitric acid at 35 – 85 °C to give **198**.

Uses. 2,5-Dimethoxynitrobenzene is reduced to 2,5-dimethoxyaniline [*102-56-7*] for use as an azo coupling component or as an intermediate for Fast Blue RR Base by benzoylation, nitration, and reduction.

2-Chlorohydroquinone dimethyl ether is similarly nitrated to give 4-chloro-2,5-dimethoxynitrobenzene [*6940-53-0*] (**199**) for reduction to 4-chloro-2,5-dimethoxyaniline [*6358-64-1*].

2,5-Diethoxynitrobenzene [*119-23-3*] (**200**), 2-nitrohydroquinone diethyl ether, 1,4-diethoxy-2-nitrobenzene, $C_{10}H_{13}NO_4$, M_r 211.16.

198

199

200

Production. 1,4-Diethoxybenzene is nitrated in a manner similar to the dimethyl ether to give **200**.

Uses. Reduction of **200** yields 2,5-diethoxyaniline [*94-85-9*], which is used as an azo coupling component or as the intermediate for Fast Blue BB Base by consecutive benzoylation, nitration, and reduction.

7.2. Nitroalkylphenols

Many mono- and dinitrocresols are available, but only those that can be produced economically by nitrosation or nitration of readily available cresols are significant. The next most accessible group of nitrocresols is obtained by diazotization of nitrotoluidines. Phenols substituted with higher alkyl groups are readily available, and certain of their nitro derivatives are used as agrochemicals.

4-Nitro-*m*-cresol [*2581-34-2*] (**201**), 1-hydroxy-3-methyl-4-nitrobenzene, $C_7H_7NO_3$, M_r 153.13, *mp* 128 – 129 °C, *bp* > 200 °C (101 kPa, decomp.), flash point ca. 110 °C, ignition temperature 455 °C, crystallizes as yellow needles, which are sparingly soluble in water and readily soluble in alcohol, chloroform, or benzene.

Production. *m*-Cresol is nitrosated in isopropanol solution and the isolated 4-nitroso-*m*-cresol is treated with aqueous nitric acid to oxidize it to **201**.

Uses. The derived insecticide metathion (fenitrothion) [*122-14-5*] (**202**), an analogue of methylparathion, is less toxic than parathion (**192**).

2-Nitro-*p*-cresol [*119-33-5*] (**203**), 1-hydroxy-4-methyl-2-nitrobenzene, $C_7H_7NO_3$, M_r 153.13, *mp* 33 °C, *bp* 125 °C (2.9 kPa), forms yellow needles, which are sparingly soluble in water and readily soluble in alcohol or benzene.

Production. *p*-Toluidine is diazotized and hydrolyzed to *p*-cresol, which in the presence of nitrous acid forms 2-nitroso-*p*-cresol; the latter is readily oxidized in situ to **203** by addition of aqueous nitric acid [1].

Uses. Treatment of an aqueous alkaline solution of 2-nitro-*p*-cresol with methyl chloride under pressure gives the methyl ether (**204**), which is reduced (Fe – formic acid) to cresidine (**83**). This azo coupling component is also available by an alternative process from the less readily

available 4-chloro-3-nitrotoluene (**81**; see Section 4.3).

4,6-Dinitro-*o*-cresol [*534-52-1*] (**205**), DNOC, 2-methyl-4,6-dinitrophenol, 2-hydroxy-1-methyl-3,5-dinitrobenzene, $C_7H_6N_2O_5$, M_r 198.13, *mp* 86.5 °C, forms yellow crystals. The compound is sparingly soluble in water and readily soluble in alcohol, ether, or benzene.

Production. *o*-Cresol is sulfonated in excess 75 % sulfuric acid to give the disulfonic acid. The sulfonation mass is diluted with water, and 2 equivalents of nitric acid are added at 70 °C to form the dinitro derivative. The product is separated while molten and washed with hot water.

Uses. 4,6-Dinitro-*o*-cresol has been used since the 1930s as a contact herbicide, being gradually displaced by improved products, some of which have related structures. Examples are dinoseb (2-*sec*-butyl-4,6-dinitrophenol) [*88-85-7*] (**206**; R = *sec*-butyl) and dinoterb (2-*tert*-butyl-4,6-dinitrophenol) [*1420-07-1*] (**206**; R = *tert*-butyl), which are produced by controlled nitration of the corresponding alkylphenol. Members of this class of dinitro compounds have also been used as insecticides and acaricides, with dinocap [*39300-45-3*] (**206**, crotonate, R = 1-methylheptyl) specifically claimed to be effective against fruit mildew.

2,6-Dinitro-*p*-cresol [*609-93-8*] (**207**), 4-methyl-2,6-dinitrophenol, 4-hydroxy-1-methyl-3,5-dinitrobenzene, $C_7H_6N_2O_5$, M_r 198.13, *mp* 82 °C, forms yellow crystals.

Production. *p*-Cresol is dinitrated directly in dilute sulfuric acid solution by careful addition of nitric acid to yield 2,6-dinitro-*p*-cresol.

Uses. 2,6-Dinitro-*p*-cresol and analogous alkyl compounds have been used as agrochemicals similarly to the 4,6-dinitro-*p*-cresol.

Toxicity of Nitrophenols and Derivatives. Nitrophenol compounds are all at least moderately toxic by inhalation and skin absorption. Nitro- and, especially, dinitrophenols and cresols are pseudoacids and must be handled accordingly. 2,4-Dinitrophenol and the dinitrocresols are more poisonous by ingestion than mononitrophenols. Detailed toxicity data are available on most of the compounds, especially the known active agents (e.g., pesticides) [22].

8. Nitroketones

Acyl substituents on the benzene ring make nitration difficult, and the isomer ratio is very sensitive to temperature and nitration conditions. Introduction of an alkyl or alkoxyl group makes nitration easier, and para substitution leads to uniform products. For example, nitration of 4-methylacetophenone gives 4-methyl-3-nitroacetophenone (**208**) in good yield. Similarly, 4-methoxypropiophenone gives the 3-nitro derivative (**209**), provided that nitration is carried out at low temperature (−5 °C). Above 0 °C, ipso nitration takes place with the formation of 2,4-dinitroanisole.

Difficult accessibility of nitroaromatic ketones together with the problem of selfcondensation of derived anilines has eliminated this class of compound from the historical colorant usage common to all other classes. Special requirements, such as pharmaceutical precursors, have a small but important place.

2-Nitroacetophenone [*577-59-3*] (**210**), $C_8H_7NO_3$, M_r 165.13, *mp* 24.5 °C, *bp* 134 °C (0.5 kPa).

Production. *O*-Acetyl-1-phenylethanol is nitrated to give a mixture of *o*- and *p*-nitrophenylethyl acetates, which are hydrolyzed with acid and fractionally distilled to yield approximately equal amounts of 1-(2-nitrophenyl)ethanol (**211**) and the corresponding 4-nitro isomer. Oxidation of **211** with dichromate – H_2SO_4 gives an 85 % yield of **210**, which can be further purified by vacuum distillation.

An alternative process involves oximination of 2-nitroethylbenzene (Section 3.5) followed by acid hydrolysis to the required product [74].

210

211

212

213

214

3-Nitroacetophenone [*121-89-1*] (**212**), 1-(3-nitrophenyl)ethanone, $C_8H_7NO_3$, M_r 165.13, *mp* 81 °C, *bp* 167 °C (2.4 kPa), crystallizes as needles from ethanol. The compound is steam volatile.

Production. Acetophenone is carefully dissolved in concentrated sulfuric acid at 0 °C, and mixed acid is added slowly below 0 °C. The crude product is precipitated by quenching into ice, filtered, and washed acid free. Purification, mainly from the ortho isomer, is achieved by recrystallization from ethanol with significant lowering of the overall yield to ca. 55 %.

4-Nitroacetophenone [*100-19-6*] (**213**), 4-nitrophenyl methyl ketone, $C_8H_7NO_3$, M_r 165.13, *mp* 80 – 81 °C, *bp* 138 °C (0.2 kPa), forms yellow prisms.

Production. 1-(4-Nitrophenyl)ethanol, coproduced with the 2-nitro compound, is oxidized with dichromate to give **213**, which is purified, if required, by recrystallization from methanol.

Uses. One of several alternative routes to synthetic chloroamphenicol (**1**) uses **213** as starting material with a first-stage bromination to α-bromo-4-nitroacetophenone [*99-81-0*] (**214**) followed by buildup of the side chain. The intermediate **214** is the key precursor in the synthesis of the bronchodilator clenbuterol [*37148-27-9*].

9. Nitroheterocycles

The chemistry of nitro derivatives of many heterocyclic systems has long been established, but their commercial exploitation has developed only since the 1930s. The more important of the diverse outlets are summarized here. Many of the compounds mentioned are likely to be covered in more detail under alternative headings (e.g., antibiotics or dyes) but not, however, compared in either synthesis or mode of action. Given the large number of nitroaryl derivatives that are used as agrochemicals, surprisingly few examples of nitroheterocyclics are reported in this field. Availability in bulk for use in one area often leads to outlets in other fine chemicals.

The nitrofuran group of broad-spectrum antibacterial drugs, based on 5-nitro-2-furaldehyde (**215**), was developed in the 1940s [75]. The less important nitroimidazole group of antibiotics was studied in the 1950s, following isolation of the naturally occurring azomycin (**216**). Also about this time, synthetic nitrothiazoles, typified by 2-acetylamino-5-nitrothiazole [*140-40-9*] (**217**), were found to have antitrichomonal activity.

215

216

217

The 1950s witnessed a change in the field of colorants with the introduction by Eastman Kodak [76] of the nitroheterocyclic-based blue disperse dye (**218**) for cellulose acetate fibers. Since then, a succession of useful nitroheterocyclic diazo components have been developed in the dyemakers continual search for high strength and more bathochromic azo dyes [77].

218

In this brief review, only those nitroheterocycles of known commercial interest are considered. This limits the systems to pyridine, quinoline, imidazole, furan, thiophene, and thiazole.

9.1. Pyridine Derivatives

Pyridine, in common with many other nitrogen heterocycles, is not rapidly nitrated because of the deactivation deriving from the protonated ring nitrogen. High-temperature nitration in oleum gives a low yield of 3-nitropyridine [*2530-26-9*]. However, pyridine *N*-oxide is nitrated under moderate conditions (mixed acid at 100 °C) [78] to give 4-nitropyridine *N*-oxide [*1124-33-0*] (**219**), which requires purification from a small quantity of the 2-isomer.

Hydrogenation of **219** under different conditions yields either the amine oxide or 4-aminopyridine [*504-24-5*]. Compound **219** is also a useful intermediate in the synthesis of many 4-substituted pyridines by facile nucleophilic displacement of the nitro group.

219

220

221

9.2. Quinoline Derivatives

Quinoline is readily nitrated in the isocyclic ring with mixed acid at 0 °C, yielding a 1 : 1 mixture of 5-nitroquinoline [*607-34-1*] (**220**) and 8-nitroquinoline [*607-35-2*] (**221**). By analogy with pyridine *N*-oxide, quinoline *N*-oxide nitrates to give the 4-nitro derivative, which is reduced to 4-nitroquinoline [*3741-15-9*] or 4-aminoquinoline [*578-68-7*], depending on the reducing agent. The 5- and 8-nitroquinolines are reduced to 5-aminoquinoline [*611-34-7*] and 8-aminoquinoline [*578-66-5*], respectively. All of these derivatives are patented in a variety of uses, many of which depend on the modified metal–ligand behavior compared to quinoline and 8-hydroxy quinoline in, for example, corrosion inhibition applications.

9.3. Imidazole Derivatives

2-Nitroimidazole [*527-73-1*] (**216**) has low toxicity and exhibits broad antibiotic activity. Many substituted nitroimidazoles have been synthesized in an attempt to clarify the structure–activity relationships of such apparently simple molecules. Synthesis of **216** is difficult and requires reaction of 2-aminoimidazole sulfate with sodium nitrite in the presence of excess copper sulfate [79]. 4-Nitroimidazole [*3034-38-6*] (4-nitroglyoxaline, **222**), containing a proportion of the 5-nitrotautomer, is more readily obtained by direct nitration of imidazole [80].

222

223

Alkylation of the sodium derivative of **222** with 2-morpholinoethyl chloride gives nimorazole [*6506-37-2*] (**223**). Similarly, 2-methylimidazole is nitrated [81] to give 2-methyl-5-nitroimidazole [*696-23-1*] (**224**), which on alkylation with 2-chloroethanol gives metronidazole [*443-48-1*] (**225**). Both of these drugs are used in the treatment of amoebiasis and trichomoniasis.

224

225

The nitro group is essential for the activity of imidazole compounds but may, however, be the cause of recently suspected carcinogenic potential of certain derivatives (see also → Imidazole and Derivatives, Chap. 7.2.).

9.4. Furan Derivatives

The use of nitrofurans as antibacterial agents was established in 1944 for the treatment of war wounds. In 1947 the same drugs were found to be effective in the prevention of coccidiosis in chickens and enteritis in swine. These and other veterinary applications led to large-volume usage in animal feed supplements.

5-Nitro-2-furaldehyde [*698-63-5*] (**215**), 2-formyl-5-nitrofuran, $C_5H_3NO_4$, M_r 141, *mp* 35 – 36 °C, *bp* 159 – 161 °C (1.3 kPa), forms crystals in petroleum ether; it is moderately soluble in water.

Production. Furfural is nitrated in acetic anhydride solution at 25 – 40 °C to give the diacetate [*92-55-7*] (**226**), which is purified by recrystallization from isopropanol and then used directly for the production of derived drugs [82].

Uses. Derivatives of **215** used as antibacterial agents include the semicarbazone nitrofurazone [*59-87-0*] (**227**) and the other hydrazones nitrofurantoin [*67-20-9*] (**228**) and furazolidone [*67-45-8*] (**229**), all containing the same active center. The mode of action is not known but probably involves an unstable reduction product. High activity is offset by the general toxicity of the class, and reports of mutagenic and carcinogenic activity have discouraged their use.

226

227

228

229

230

9.5. Thiophene Derivatives

Thiophenes are used less commonly than furans as chemotherapeutic agents, although nifurzide [*39978-42-2*] (**230**), obtained by condensation of 5-nitrothiophene-2-carboxylic acid hydrazide with 3-(2-nitro-5-furyl) acrolein, contains both a nitrofuran and a nitrothiophene residue.

Thiophene itself is nitrated to 2-nitrothiophene by gradual addition of a solution of thiophene in acetic anhydride to a mixture of nitric and glacial acetic acids at 10 °C. Attempts to circumvent acetyl nitrate processes are reported to be both difficult and dangerous. Substituted thiophenes more amenable to nitration are limited. 2-Acetylthiophene is nitrated with acetyl nitrate to give 2-nitro-5-acetylthiophene (**231**), the derived amine of which has been compared with 2-amino-3-nitro-5-acetylthiophene (**232**) as a diazo component in azo disperse dyes [83]. The latter is prepared by amination of 2-chloro-3-nitro-5-acetylthiophene; the derived dyes would have been of commercial interest if a more economical route had existed [77].

The Gewald synthesis of substituted 2-aminothiophenes [84] made 2-acetylamino-3-thiophenecarboxylic acid ethyl ester readily available for mononitration, with mixed acid at 0 – 5 °C, to give 2-amino-3-ethoxycarbonyl-5-nitrothiophene [*42783-04-0*] (**233**) [85] after deacylation. Similarly, the *N*-acetyl derivative of the readily available 2-amino-3-thiophenecarboxylic acid is dinitrated with mixed acid at 0 °C, with decarboxylation and deacylation to give 2-amino-3,5-dinitrothiophene [*2045-70-7*] (**234**) [86]. Monoazo dyes derived from **234** yield important blue and green shades on polyester, e.g., C.I. Disperse Green 9 (**235**) with λ_{max} 614 nm (cf. Table 11).

233

234

235

9.6. Thiazole Derivatives

2-Amino-5-nitrothiazole [*121-66-4*] (**236**), 5-nitro-2-thiazolamine, Enheptin, Entramin, $C_3H_3N_3O_2S$, M_r 145, *mp* 200 °C.

Production. Early production of **236** was based on nitration of 2-acetylaminothiazole and careful hydrolysis [87]. Direct nitration of 2-aminothiazole gives a cleaner product and is

best achieved by adding 2-aminothiazole nitrate [*57530-25-3*] to concentrated sulfuric acid at 0–10 °C [88]. This process and the nitration of *o*-anisidine are the only large-scale processes based on rearrangement of an amine nitrate, and both are potentially hazardous due to the possibility of runaway exothermic reactions [89].

Uses. Although **236** has been used as a selective chemotherapeutic agent, the *N*-formyl derivative, forminitrazole [*500-08-3*] and the *N*-acetyl derivative, acinitrazole [*140-40-9*] (**217**) are more important, being used in the treatment of trichomoniasis and as a veterinary antibacterial, respectively. The derivative niridazole [*61-57-4*] (**237**), used in the treatment of schistosomiasis, is obtained by reaction of **236** with 2-chloroethyl isocyanate followed by ring closure [88]. The antiparasitic thenitrazole [*3810-35-3*] (**238**) is obtained by acylation of **236** with 2-thenoyl chloride in pyridine.

236

237

238

Production of dye **218** (C.I. Disperse Blue 106) has resulted in the synthesis of many analogous dyes [76,77,90], but with only marginal improvement in specific properties. Diazotization of **236** with nitrosylsulfuric acid, followed by coupling with tertiary arylamines, gives azo products in yields of 50–60 %. Improvements in both yield and purity are claimed to result from using displacement coupling, for example, with 4-formyl- or 4- carboxylarylamine coupling components [91].

Benzothiazole and Benzoisothiazole Derivatives. Nitroamino derivatives of benzothiazole and benzoisothiazole have both been used as diazo components. For example, **239**, derived from 2-amino-6-nitrobenzothiazole [*6285-57-0*], is a valuable bluish red dye for polyester. It is bathochromic to the extent of 68 nm in the visible spectrum, compared with the corresponding dye obtained from 4-nitroaniline [92], thus demonstrating the comparatively low polarizing effect of a nitro substituent in an aromatic ring compared with a nitro substituent in a heterocyclic ring, e.g., in dyes derived from **236**. The acylic substituted products are, however, more thermally stable and have superior lightfastness. Blue and greenish blue dyes based on 7-amino-5-nitrobenz [3,4-*c*] isothiazole (**240**) are more important because the *o*-quinonoid structure leads to more bathochromic colors than those based on **236**, while having good fastness properties [93]. Synthesis of **240** occurs by treatment of 2-cyano-4-nitroaniline (**130**) with sulfide, followed by oxidative cyclization of the derived thioamide with hydrogen peroxide [94].

1. History

Nitrogen was discovered ca. 1770, independently by SCHEELE and PRIESTLEY, as a constituent of air that does not support respiration or combustion. LAVOISIER gave it the name azôte (from the Greek, "lifeless"). After niter and nitric acid were recognized as compounds of the element, the name nitrogenium (Latin, "niter former") was introduced. In 1784 CAVENDISH produced nitrogen oxides from nitrogen and oxygen using an electrical discharge. Not until the 1900s did atmospheric nitrogen come into large-scale use for the production of calcium nitrate (FRANK and CARO, 1902), nitric acid (BIRKELAND and EYDE, 1905), ammonia (HABER and BOSCH, 1908), and nitric acid by ammonia oxidation (OSTWALD and BAUER, 1914). Nitrogen was first liquefied by CAILLETET in 1877; large-scale nitrogen production by the rectification of liquid air began in 1902 (VON LINDE).

2. Properties

Nitrogen, N, atomic number 7, A_r 14.0067, has the electron configuration $1s^2 2s^2 2p^3$. It is the lightest element in group 15 of the periodic table. In compounds, nitrogen occurs in the oxidation states +5 to −3, with +5, +3, and −3 being preferred.

Elemental nitrogen forms a stable diatomic molecule, known as molecular nitrogen or dinitrogen [*7727-37-9*].

Physical Properties. At atmospheric pressure and room temperature, nitrogen is a colorless, odorless, noncombustible gas. At 0 °C and 101.3 kPa, 1 L of nitrogen weighs 1.2505 g. Nitrogen condenses to a colorless liquid at −195.80 °C and 101.3 kPa and forms a white solid at −209.86 °C.

Nitrogen is diamagnetic in all states of aggregation; the magnetic susceptibility at room temperature is -12.0×10^{-6} cm^3/mol. Some physical properties of nitrogen (comprehensive data are given in [1–12]) are as follows:

M_r	28.0134
N – N bond length	109.4 pm
Triple point	
T	63.15 K
p	12.463 kPa
ϱ_g; ϱ_l; ϱ_s	0.6803; 867.7; 947 g/L
heat of fusion	25.8 kJ/kg
Boiling point (101.3 kPa)	77.35 K
ϱ_g; ϱ_l	4.61; 808.6 g/L
heat of vaporization	199 kJ/kg
Critical point	
T_{crit}	126.2 K
p_{crit}	3.39908 MPa
ϱ_{crit}	314.03 g/L
1st ionization energy	15.58 eV
Properties at 0 °C, 101.3 kPa:	
ϱ	1.2505 g/L
Relative density (air = 1)	0.967
Specific heat capacity	1.039 J g^{-1} K^{-1}
Dynamic viscosity	15.9×10^{-6} Pa · s
Thermal conductivity	23.86 mW m^{-1} K^{-1}
Real gas factor pV/RT	0.9995

[a] At saturation, the first figures are properties of the liquid, the second figures are properties of the coexisting gaseous state.
[b] The values for the enthalpy H_0 and entropy S_0 at the reference state temperature $T = 298.15$ K are $H_0 = 8669.0$ J/mol and $S_0 = 191.502$ J mol^{-1} K^{-1}.
[c] Triple point.
[d] Critical point.

Table 2. Physical properties of solid nitrogen

Modification	Existence range, K	Crystal structure	ϱ, g/L	Vapor pressure, kPa
β	35.6 – 63.15	hexagonal	948 [a]	6.3 [a]
α	0 – 35.6	cubic	1027 [b]	1.47×10^{-11} [b]

[a] At 60 K.
[b] At 21.2 K.

Table 1 lists properties of gaseous and liquid nitrogen as a function of temperature, while some properties of solid nitrogen are given in Table 2. Figure 1 shows the vapor-pressure curve between the triple point and the critical point; Figure 2 is the enthalpy – temperature diagram.

Nitrogen has little solubility in liquids. Table 3 lists some values; for a comprehensive summary, see [15]. The solubility of nitrogen in molten metals is important in the production of some steels.

The diffusion constants for nitrogen in gases at ambient temperatures lie in the range of 0.1 – 1 cm^2/s (20 °C); in liquids, $< 10^{-4}$ cm^2/s; in solids, $< 10^{-10}$ cm^2/s. Table 4 (see page 4) lists some values.

For equilibrium data on the adsorption of nitrogen on various adsorbents, see [20, 21].

The boiling equilibria of O_2–N_2 and O_2–N_2–Ar mixtures form the basis for the low-temperature distillation of air [22, 23]; the separation of nitrogen from natural gas depends on those of nitrogen – hydrocarbon mixtures [22].

Figure 1. Vapor pressure of nitrogen

Figure 2. Enthalpy – temperature diagram of nitrogen
The heat absorption of liquid nitrogen on vaporization and subsequent heating of the cold gas can be determined from this equilibrium diagram. For example, at a pressure of 1 bar, the heat of vaporization is ca. 248 kJ/m^3 , and the heat required to warm the cold gas from 77 K to 288 K (15 °C) is 518 − 248 = 270 kJ/m^3 (1 kJ = 0.239 kcal)

Table 3. Solubility of nitrogen (further values: [13–15])

Solvent	T, °C	pN_2, MPa	Solubility, mol N_2/kg
Water	0	0.1	1.04×10^{-3}
	25	0.1	6.2×10^{-4}
	25	10	5.6×10^{-2}
	25	100	0.32
Ethanol	20	0.1	6.8×10^{-3}
Ethyl acetate	20	0.1	8.6×10^{-3}
Blood	38	0.1	6.2×10^{-4} mol/L
Olive oil	22	0.1	2.3×10^{-3} mol/L
γ-Iron	1000	0.1	8×10^{-3}

Table 4. Diffusion constants of nitrogen (further values: [16–18])

Diffusion medium	T, °C	D, cm^2/s
Nitrogen [a]	0	0.174
Hydrogen	20	0.77
Oxygen	20	0.219
Water vapor	20	0.23
Water	18	1.6×10^{-5}
Seawater	23.5	1.9×10^{-5}
α-Fe [b]	500	7.3×10^{-9}
Molten iron [b] [19]	1600	7.5×10^{-5}

[a] Self-diffusion.
[b] Diffusion as atomic N.

Table 5. Typical specific energy consumptions for the production of nitrogen gas at 8 bar (abs.) in a single- and double-column process (for standard purities)

	Single-column process, kWh/m^3 (STP) N_2	Double-column process, kWh/m^3 (STP) N_2
Air compression	0.25	0.13
N_2 compression		0.09
Total compression	*0.25*	*0.22*

Isotopes. Natural nitrogen contains the isotopes ^{14}N (A_r 14.00307) and ^{15}N (15.00011); the abundances in atmospheric nitrogen are 99.64 vol % and 0.36 vol %, respectively. The isotopic concentrations may differ in other gases, such as natural gas.

The artifical nitrogen isotopes have short half-lives: 0.011 s (^{12}N), 10 min (^{13}N), 7.2 s (^{16}N), 4.16 s (^{17}N), and 0.63 s (^{18}N). The most important processes for enriching the natural isotopes are countercurrent distillation of nitrogen monoxide and the $NO-HNO_3$ exchange process (Spindel – Taylor process) [24, 25]. Other methods are the laser-induced decomposition of tetrazine $C_2H_2N_4$ to give N_2 and HCN, which enriches $^{15}N^{14}N$ (and $H^{13}CN$) [26], and the continuous isotope separation by use of an ionexchange resin [27].

Chemical Properties. Nitrogen has an extremely high heat of dissociation:

$$N_2 \rightleftharpoons 2\,N \quad \Delta H_0 = 943.8\ kJ/mol$$

No marked dissociation takes place even at 3000 °C and standard pressure. The equilibrium constant for the thermal dissociation of molecular nitrogen is $K \approx 10^{-120}$ at 25 °C and $K \approx 10^{-6}$ even at 3000 °C. The $N\equiv N$ triple bond is nonpolar and has a significantly higher ionization potential than other comparable triple-bond systems. The strength of the $N\equiv N$ bond is responsible for the inertness of N_2.

Nitrogen reacts with lithium at room temperature, and also with calcium and magnesium at elevated temperatures, to form nitrides. Many other metals, such as Al, Ti, V, and Cr, combine directly with nitrogen at red heat, also forming nitrides. With boron, the product is boron nitride (→ Boron Carbide, Boron Nitride, and Metal Borides, Chap. 2.).

Important reactions of nitrogen with nonmetals are those with hydrogen, yielding ammonia (→ Ammonia), and with oxygen. The latter, an endothermic reaction, gives nitrogen monoxide:

$$N_2 + O_2 \rightleftharpoons 2\,NO \quad \Delta H_0 = 180\ kJ/mol$$

and has long been utilized for the production of nitric acid (→ Nitric Acid, Nitrous Acid, and Nitrogen Oxides). The reaction of nitrogen with calcium carbide leads to calcium cyanamide.

Nitrogen appears in a variety of forms in organic chemistry, such as amines, amides, nitriles, oximes, and also N-heterocyclic compounds. Naturally occurring polymers containing nitrogen are proteins and nucleic acids; those of synthetic origin include polyamides, polyimides, polyacrylonitrile, polyurethanes, and melamine and urea resins.

Compounds of trivalent nitrogen with coordination number 3 usually have a pyramidal molecular structure, one orbital of the sp^3 hybrid being occupied by an electron lone pair. Molecules of this type undergo inversion in which the N atom moves back and forth through the plane formed by the three covalently bonded ligands. The inversion barrier in NH_3 is only 25 kJ/mol.

The lone pair imparts donor properties to covalently bonded trivalent nitrogen. Since nitrogen is one of the most electronegative elements, it readily forms hydrogen bonds in its compounds with hydrogen.

The nitrogen molecule, often referred to as dinitrogen, is isoelectronic with carbon monoxide and acetylene. Transition metal dinitrogen complexes were first prepared in 1965. By now more than 100 are known [28]. The transition metals such as Mo, Cr, Co, Ni, Ti, and the platinum group metals can fix nitrogen in dinitrogen complexes (chemical nitrogen fixation). Most of

these exhibit end-on bonding of the dinitrogen molecule, but examples of side-on complexes have also been found [29].

Molecular nitrogen can also be fixed biologically by microorganisms. Both routes have been studied extensively in recent research (→ Nitrogen Fixation).

Active or atomic nitrogen can be prepared by silent electrical discharge in flowing nitrogen and at low pressures. Its persistent characteristic yellow afterglow (Lewis – Rayleigh afterglow) indicates that the recombination of the atomic to the molecular form is slow. In contrast to the largely inert N_2, active nitrogen reacts with numerous elements, as well as with inorganic and organic compounds. Most of the reactions are attributed to nitrogen atoms, but electronically excited molecules are also involved. A summary is given in [30].

3. Occurrence

The Earth's atmosphere contains ca. 78 vol % nitrogen, which is partly dissociated to atomic nitrogen at high altitudes by ultraviolet radiation. Electrical discharges (in storms) generate nitrogen oxides, which are transported to the soil by rain (ca. 1 kg of nitrate nitrogen per hectare of soil per year). Nitrogen is also present in natural gas, inclusions in rocks, and water (dissolved). Because of the high solubility of most nitrates, minerals containing nitrogen are rare; important reserves include the nitrate deposits in Chile (Chile saltpeter). The estimated total nitrogen abundance in the outer crust is 0.03 wt %.

Organically fixed nitrogen is present in the proteins of all living things and is liberated by biodegradation and excretion. The human body contains ca. 3 wt % N.

Nitrogen and its compounds also occur extraterrestrially. Nitrogen has been found in meteorite inclusions. Nitrogen has been detected in the atmosphere of Mars (2.7 vol %), Venus (3.5 vol %), on Pluto, and possibly in traces on Mercury.

4. Production

Nitrogen is obtained from air. The processes used to separate nitrogen from air can be classified as cryogenic (low-temperature) processes, adsorption processes, and membrane separation. Older methods, such as the chemical removal of oxygen from air, are of second importance.

The selection of separation technology for a particular application is dependent on the specific use requirements for the gas. While cryogenic separation can meet almost all product requirements, this is not the case for adsorption and membranes. The present relative cost effectiveness of various technologies for nitrogen at smaller capacities is illustrated by a purity versus capacity plot in Figure 3. The pace of technological development has been rapid since the 1970s for both cryogenic and noncryogenic technologies.

Figure 3. Areas of cost effective nitrogen production in a purity versus capacity plot [31]

4.1. Cryogenic Air Separation

Principles. To separate air by rectification, part of it must be liquefied. This can only be achieved below the critical point $T_{crit} = 132.5$ K and $p_{crit} = 37.7$ bar. The vapor pressure curves of air constituents indicate that air condenses under ambient pressure (1 bar) at a temperature of 81.5 K (− 192 °C), whereas at 6 bar only 101 K (− 172 °C) is required. To cool 1 kg of air from + 15 to − 196 °C requires ca. 415 kJ. The refrigeration required can be provided by expansion in a throttle, by the Joule – Thomson effect, or by using a turbo expander, which produces a greater amount of refrigeration energy. Starting at ambient temperature, neither effect is in itself sufficient to produce liquid air; therefore, countercurrent precooling must be used to lower the temperature to a suitable level.

Figure 4. Vapor pressure curves of nitrogen and oxygen
The temperature difference ΔT required for heat transfer determines the operating pressures of the high- and low-pressure columns [33]

Separation of air components is performed by cryogenic rectification (→ Cryogenic Technology, Chap. 6.4.). The simplest system is the single-column process. It is used to produce gaseous nitrogen and small amounts of liquid nitrogen. If both nitrogen and oxygen products are required, the double-column process is used. The principle of double-column rectification combines the condenser of the high-pressure column (HP column) with the reboiler of the low-pressure column (LP column) in a single heat-transfer apparatus. To provide a sufficient heat-transfer rate, a temperature difference of about 2 K is required. Therefore, the columns are operated at different pressures. Figure 4 outlines the relations between the vapor pressures of oxygen and nitrogen, temperature difference and resulting operating pressures at which most double-column processes are operated. Comprehensive information is given in [32, 33].

Single-Column Process. Figure 5 shows a flow sheet of a cryogenic air separator for nitrogen with a single rectification column and molecular sieve adsorbers for front-end purification. The air separator described here is suitable for the production of both gaseous and liquid nitrogen.

Air is filtered (a) and compressed in a compressor (b), then cooled against water and/or chilled water in a tube-type or direct-contact cooler (c). After the condensed water has been removed by a scrubber or a demister (d), the air enters the zeolite adsorbers (e), where water, carbon dioxide, and other impurities (e.g., hydrocarbons) are removed. These units are usually designed as duplex adsorbers and automatically switched from adsorption to regeneration and vice versa. In the heat exchanger (g), the air is cooled almost to its liquefaction temperature in countercurrent to gaseous nitrogen product and residual gas. The air enters the rectification column (i) with an operating pressure of about 6 – 10 bar, where it is separated into pure nitrogen at the top and oxygen-enriched liquid at the bottom. Part of the gaseous nitrogen is product nitrogen at column pressure. The gaseous nitrogen that is not withdrawn at the top of the rectification column is fed to the evaporator/condenser (k). In the evaporator/condenser oxygen-enriched liquid at low pressure is evaporated from the liquid, the heat required is provided by nitrogen condensing at column pressure. Part of the liquid nitrogen is used to maintain the necessary reflux for air separation in the distillation column, part of it can be withdrawn as liquid nitrogen product.

The evaporated oxygen-enriched liquid leaves the evaporator/condenser as residual gas, is warmed in the heat exchanger, and enters the expansion turbine (h). The refrigeration maintained in the expander covers the cold losses as well as the refrigeration requirement for nitrogen liquefaction. After expansion of the residual gas to nearly atmospheric pressure, it is used as

Figure 5. Flow sheet of a cryogenic air separator for production of gaseous and liquid nitrogen, single column process

the regeneration gas for the molecular sieve adsorbers. This single-column process is normally selected for small and medium-sized units for producing nitrogen gas and liquid at a pressure suitable for final use, so that no additional product compressor is required. Commercial plants produce nitrogen containing about 1 ppm O_2 (by volume), argon, and, depending on the contents in the feed air, hydrogen, and carbon monoxide.

Rectification columns are equipped with internal trays or, more recently, structured packings. Because of the reduced pressure drop, this design results in increased flexibility in plant load.

Figure 6. Flow sheet of a cryogenic air separator for production of gaseous and liquid nitrogen, double column process
a) Air filter; b) Air compressor; c_1, c_2) Air cooler; d) Scrubber or demister; e) Adsorber; f) Heater; g) Heat exchanger; h) Expansion turbine; i) Rectification columns with sieve trays (i_1) High-pressure column; i_2) Low-pressure column); k) Evaporator/condenser; l) Subcooler

Double-Column Process. Figure 6 (see next page) shows the flow sheet of a cryogenic air separator for nitrogen production by a double-column rectification process. The compression and purification of the air is as for the single-column process.

In the high-pressure column (HP column, i_1) the air is preseparated into pure nitrogen and oxygen-enriched liquid. In the low-pressure column (LP column, i_2), final separation into pur oxygen as bottom product and pure nitrogen at the top occurs. The gaseous nitrogen at the top

of the HP column is condensed in the evaporator/condenser (k). Part of it serves as reflux for the HP column, and the remainder is subcooled, expanded, and uses as reflux for the LP column. Liquid nitrogen product can be withdrawn from the top of the HP column (at high pressure) or, alternatively, from the top of the LP column (at low pressure). Pure gaseous nitrogen is withdrawn from the top of the LP column and warmed in the subcooler (l) and the heat exchanger (g). In addition, pure gaseous high pressure nitrogen is withdrawn from the HP column. Oxygen-enriched liquid at the bottom of the HP column is subcooled and expanded in the middle section of the LP column as feed flow.

Figure 7. Double-column process – three-dimensional inside view of a cold box

To maintain the refrigeration, a sidestream of air is drawn from the heat exchanger to the expansion turbine (h), expanded, and fed to the middle section of the LP column. Impure oxygen gas from the LP column and expanded air from the turbine are mixed and used to regenerate the molecular sieve adsorbers (e) after being heated in the heat exchanger.

All low-temperature equipment is assembled in an insulated cold box construction in order to minimize cold losses.

Figure 7 shows a three-dimensional inside view of a cold box structure.

Figure 8. Nitrogen liquefaction unit with two expansion turbines for gas
$a_1) - a_4)$ compressors; $b_1) - b_4)$ Water coolers; c) Heat exchanger and subcooler; $d_1)$, $d_2)$ Expansion turbines; e) Liquid nitrogen vessel

Power Consumption. The specific energy consumptions of nitrogen generators range from 0.1 kWh/m^3 N_2 to 0.3 kWh/m^3 N_2 for the gas and depend on capacity and pressure. Table 5 lists typical specific energy consumptions in a single- and a double-column process. To achieve the same pressure level as the nitrogen gas at the

output, the nitrogen gas in the double-column process has to be further compressed by a product compressor. The total specific energy consumption is lower in the double-column process. The choice of process depends on the nitrogen capacity and pressure required, and a comparison of investment and operation costs is necessary.

Nitrogen Liquefaction. To obtain the entire nitrogen product in liquid form, additional refrigeration and liquefaction equipment is required. Several types of liquefaction units are possible. Integrated liquefiers are designed as part of the air-separation unit. In many cases liquefiers are built separately. Standard liquefier types include a process with a single turbine. Nitrogen is admitted as gaseous feed. Such liquefiers are suitable for small or medium amounts.

Figure 8 shows a schematic of a two-turbine nitrogen liquefier. Gaseous nitrogen is compressed from ambient pressure to about 600 kPa in a_1, mixed with medium-pressure recycle nitrogen, boosted to about 2800 kPa in a_2, and then further boosted isothermically in compressors a_3 and a_4 driven by expansion turbines, with aftercoolers to 5800 kPa. Refrigeration is obtained by expanding sidestreams of high-pressure nitrogen in the turbines d_1 and d_2 to a medium pressure level. The main nitrogen stream, which after exchanger c is well below its critical temperature, is expanded by a throttle valve and forms a vapor and liquid phase. Phase separation is performed in vessel e, from where product liquid is withdrawn.

Cold cascades with separate or mixed loops are used in large liquefaction units. The advantage of a cascade is that it has a specific energy consumption for liquid nitrogen (ca. 0.5–0.6 kWh/m^3 N_2) lower than that of the nitrogen loop described above (ca. 0.8 kWh/m^3 N_2) [34, 35].

Purification Methods. Nitrogen production by cryogenic distillation of air inherently produces a product of high purity. It removes virtually all bulk and trace gases whose boiling points are well above that of nitrogen. Methane, water, and carbon dioxide are removed to less than ppb levels by volume. The very low boiling gases helium, hydrogen, and neon are not removed by standard single-column cryogenic processes, and nor is carbon monoxide, which is difficult to separate by cryogenic fractionation because of its boiling point of 81.6 K. Several purification systems have been developed to produce ultrahigh-purity nitrogen to comply with specifications in the sub-ppb level. Front-end purification prior to the cryogenic nitrogen generator as well as downstream purifier systems are used.

CO and H_2 can be removed from the compressed air before distillation by oxidation in an upstream catalytic reactor with a noble metal catalyst. The oxidation products water and carbon dioxide are removed by the conventional air-purification system. The distillation section is then designed to remove oxygen (and Ar if necessary) down to less than 1 ppb [36].

Downstream purifier systems operate by oxidation over metal oxides, primarily manganese oxide, which is capable of oxidizing carbon monxide, and chemisorption by transition metals. Thus, nickel at ambient temperature eliminates oxygen as the oxide and hydrogen as the hydride. Higher pressures favor more effective contaminant removal. Finally, a filter system is installed to remove particles. Typically, very high performance, series/parallel canister filters of electropolished stainless steel are used. Particulate loadings on the order of 0.35 particles per liter with a diameter greater than 0.01 µm are achieved. Purifier systems are described in [37] and [38].

New purification concepts using systems of the getter or cryoadsorber type are under development [39].

4.2. Air Separation by Adsorption

Nitrogen production by pressure-swing adsorption (PSA) employs carbon molecular sieves or zeolitic molecular sieves. Carbon molecular sieves were developed by Bergbauforschung of Germany. Today modified carbon molecular sieves are produced by a number of other firms after expiration of the original patents. Zeolitic molecular sieves were first produced on an industrial scale by Union Carbide in the United States. These materials are employed in various processes for the separation and purification of gases and liquids; however, up to now they have not been used extensively for the production of

nitrogen. Separation of air components with zeolites is based on differences in adsorption capacity; with carbon molecular sieves, on differences in diffusion rate. Nitrogen is produced mainly on carbon molecular sieves, whereby the unadsorbed N_2-rich product gas is withdrawn at the discharge end of the adsorber during the adsorption phase [40–42]. In the zeolite process, previously adsorbed nitrogen is recovered by lowering the pressure during the regeneration phase.

Figure 9. Schematic of a PSA plant for the production of nitrogen from air on carbon molecular sieve
a) Compressor; b) Heat exchanger; c) Condensate separator; d_1), d_2) Adsorbers; e) Buffer vessel

Figure 10. Pressure swing adsorption unit for production of 1400 m^3 nitrogen (STD) (Linde AG, Höllriegelskreuth)

Figure 9 shows schematically a PSA nitrogen unit. The feed air is compressed to 5 – 12 bar, passed through a water-cooled heat exchanger and a condensate separator, and then fed to the adsorbers (d), which alternate between adsorption and regeneration. Water, carbon dioxide, and oxygen are removed by adsorption on carbon molecular sieves. The unadsorbed nitrogen leaves the adsorber during the adsorption phase, goes to a buffer vessel (e) at 4 – 11 bar (i.e., ca. 1 bar below the selected inlet pressure) and is delivered from the vessel. At the same time, the second adsorber is being regenerated by pressure reduction. In principle, the pressure level during the adsorption and regeneration phase can also be lowered; the compressor is replaced by a blower, and a vacuum pump is used to reduce the pressure for regeneration. Figure 10 shows a unit with a capacity of 1400 m^3 nitrogen (STP) containing 1 vol % residual O_2.

The PSA process can economically produce nitrogen with a residual oxygen content of 100 ppm by volume without further catalytic treatment. By employing newly developed carbon molecular sieves, it is even possible to reduce the residual oxygen content in the nitrogen product gas to less than 10 ppm. The dew point is − 60 to − 70 °C, and the CO_2 content is below 5 ppm by volume [43].

The production capacity depends on the required purity and the permissible residual O_2 content in the product. For example, if the O_2 level in the product is raised from 0.5 to 2 vol %, the capacity doubles. The specific energy requirement for producing nitrogen by the BF process at 3 vol % residual oxygen is 0.2 kWh/kg N_2; at 1000 ppm oxygen by volume, 0.5 kWh/kg N_2. By utilizing newer carbon molecular sieves with improved separation properties, the above values can be reduced by as much as 20 %.

4.3. Nitrogen Production by Membrane Separation

Membranes can also be used for the separation of oxygen and nitrogen. For detailed physical and design principles, see → Membranes and Membrane Separation Processes.

Physical Principles. Gases permeate through dense nonporous membranes by solution diffusion. The permeability coefficient P_i, which is a measure of the capacity of the membrane to transport gas species i, is the product of the Henry's law constant S_i and the diffusivity coefficient D_i for component i in the membrane material. The volumetric flux of the component

Table 6. Oxygen and nitrogen permeabilities and selectivity of selected polymers for air separation [44–47]

Polymer	Temperature, °C	Permeability, Barrer *		O_2/N_2 selectivity α
		O_2	N_2

* $1\,\mathrm{Barrer} = \frac{\mathrm{cm}^3\,(\mathrm{STP})\,\mathrm{cm}}{\mathrm{cm}^2\,\mathrm{s\,cm\,Hg}} \cdot 10^{-10}$.

through a membrane of surface area A and thickness l, whose two faces are kept at pressures p_1 and p_2 is given by

$$J_i = P_i A / l \Delta p_i$$

where Δp is the difference in partial pressures $(p_1 - p_2)$ across the membrane. The ability of a membrane to separate a pair of gases is described by the ratio of permeabilities $\alpha = P_i/P_j$, which is called the selectivity or separation factor for gaseous components i and j. Table 6 (see next page) lists the permeability coefficients and O_2/N_2 selectivities for a variety of polymers. Virtually all membranes are more permeable to oxygen than they are to nitrogen. Hence, the nitrogen product from a membrane separation stage is the retentate on the high-pressure feed side. For a monography on polymeric gas-separation membranes, see [45].

Status of Membrane Technology. Economical membrane operation requires a high flow rate (of oxygen, in the case of nitrogen production) and a O_2/N_2 selectivity of at least 4. Furthermore, a thin membrane is essential to give a high gas flux. Thin polymeric films by themselves are too weak to withstand the high differential gas pressures required. The commercial breakthrough of membranes in gas separation came with the fabrication of asymmetric and thin-film composite membranes. The separation membrane can be arranged either in spiral wound modules or in the shape of hollow fibers; the latter are normally mounted together in bundles. For the fabrication of hollow fibers see [48]. The state of the art 1990 are membrane fibers with properties as listed below [48]:

O_2/N_2 selectivity	6.0
O_2 permeability, Barrer	2.0
Skin thickness, nm	50
Membrane cost, \$/m^2	180
Feed pressure, bar	11
Permeate pressure, bar	1
Fiber geometry, µm	250 × 500
Length, m	2

The thin membrane must be virtually defect free because a higher defect area is detrimental to the selectivity α owing to Knudsen diffusion. Surface defects can be eliminated by overcoating the membrane with a 500 nm layer of a highly selective material such as silicone rubber [50].

Process Cycle Modes. Early membrane systems used single-stage processes for N_2 production, which are best suited for low-purity nitrogen. More sophisticated, multistage processes are better suited for higher purities and larger capacities. Four processes that are used for nitrogen production are shown in Figure 11. Nitrogen containing less than 10 ppm by volume of oxygen can be produced economically by using a membrane/Deoxo hybrid system; oxygen is removed by reducing it to water over a catalyst

Figure 11. Configurations of membrane processes for nitrogen production [49]

with hydrogen. The gas leaving the catalyst bed is cooled, dried, and delivered as product.

A number of hybrid processes which combine membrane and nonmembrane processes such as membrane/cryo and membrane/PSA processes have been studied and patented.

Commercial Membrane Air Separation Modules. The main components of a membrane system include the compressor, the feed-conditioning package, the membrane modules and the system controls. A schematic of a typical arrangement of these components is shown in Figure 12. Air is compressed to 6 – 15 bar, and conditioned to remove contaminants and to provide temperatures and humidity levels for optimal membrane performance. The separation unit typically comprises one or more separation stages, each consisting of one or more membrane modules in parallel.

Prepackaged systems for producing 98 % N_2 range in nominal capacity from < 10 to $> 800\,m^3$ (STP) per hour. The largest nitrogen membrane units produce 600 t/d of nitrogen, which corresponds to an hourly capacity of $20\,000\,m^3$ (STP) [51]. Commercial experience indicates unscheduled down times below 1 – 1.5 %. Given protection from organic contaminants and liquid water, membrane lifetimes may exceed 10 years or more.

A detailed method for economic evaluation of membrane based air separation is given in [52]. Prediction of membrane performance along with approximation of membrane costs and lifetime are used to calculate nitrogen enrichment costs for membrane systems. Experimental data obtained during testing various small nitrogen generators from different vendors gave electrical consumption figures from 0.7 to 0.26 kWh per m^3 (STP) of nitrogen, depending on feed air quantity, purity and nitrogen recovery. See also Table 7.

Leading suppliers of membrane nitrogen units are Permea (a Monsanto company, USA),

4.4. Oxygen Removal from Air

As an alternative to air separation, which yields not only nitrogen but also an oxygen-rich gas, an inert gas can be obtained by removing all or part of the atmospheric oxygen. In the system shown in Figure 13, fuel (natural gas, propane, NGL) is burned in a specially designed burner supplied with the stoichiometric quantity of air. The hot combustion gases exit at the bottom of the reaction chamber and are directly cooled by atomized water in countercurrent. The water is separated, the gas is dried by adsorption on silica gel, and carbon dioxide is removed on molecular sieves. Apart from nitrogen and the noble gases initially present in the air, the product gas contains less than 0.1 vol % CO_2; it has $CO + H_2 < 0.01$ vol % and $O_2 < 0.5$ vol % for oxidizing burner operation, or $CO + H_2 < 0.7$ vol % and $O_2 < 0.01$ vol % for reducing operation; the dew point is $-50\,°C$. The unit shown in Figure 13, with a capacity of 1000 m^3/h N_2 (STP), consumes 117 m^3/h of methane or 46 m^3/h of propane (STP), 75 m^3/h of cooling water, and 9 kW of power [59].

In a similar way, atmospheric oxygen can be removed through the combustion of hydrogen or ammonia, the latter according to:

$$4\,NH_3 + 3\,O_2 \rightarrow 2\,N_2 + 6\,H_2O$$

with subsequent separation of water [60]. Nitrogen or a nitrogen – hydrogen mixture containing 0 – 75 vol % H_2 can also be obtained by catalytically cracking ammonia to give nitrogen and hydrogen (nickel catalyst, 800 °C; for more details → Hydrogen, Chap. 4.5.2.) and then burning the hydrogen. The cracked ammonia atmosphere is used, for example, in the surface treatment of steels.

5. Storage and Transportation

Major consumers usually produce nitrogen on site (captive nitrogen). With the development of PSA and membrane processes on-site production of smaller amounts of nitrogen is becoming increasingly feasible.

Merchant nitrogen can be stored and transported in gaseous form or as liquid nitrogen at cryogenic temperatures. In Germany, the latter is often designated LIN. The principle logistics for nitrogen (and oxygen) storage and transportation are shown in Figure 14 (see next page).

Small quantities of gaseous nitrogen are usually stored and shipped in high pressure cylinders or cylinder clusters. The charging pressure of a standard cylinder (50 L in Germany) is 200 bar, corresponding to 10 m^3 (STP) of gas. For shipping of small quantities of liquid nitrogen, insulated transportation and storage vessels are available. Large quantities are transported in road and rail tankers. Typical vacuum insulated tanker trucks can carry 10 – 22 t of liquid nitrogen with a maximum pressure of 1.7 bar. The higher cost of liquefaction is partly offset by lower transportation costs due to smaller volume and weight.

At the consumer site nitrogen is usually stored in vacuum-insulated storage tanks. The available capacities range from 3 to 80 m^3 carrying 4.6 – 95 t of liquid nitrogen and giving 2000 – 52 000 m^3 (1 bar, 15 °C) of gaseous product upon vaporization. Depending on the pres-

Figure 14. Nitrogen distribution from production to consumer

sure required for use, tank vessels with different operating pressures are available (e.g., 18 or 36 bar). Evaporation losses are between 0.6 and 0.15 % per day, depending on the capacity. Figure 15 shows a medium-sized tank vessel and a liquid nitrogen road tanker during filling operation.

Liquid nitrogen can be consumed directly as a liquid to utilize the cold; for users of gaseous nitrogen liquid nitrogen is vaporized in fin-tube heat exchangers heated by ambient air. Figure 16 illustrates schematically the design of such a cryogenic gasifier for liquid nitrogen.

Figure 15. Liquid nitrogen storage tank and transportation truck during filling operation

Figure 16. Schematic of a liquid storage vessel with cryogenic gasifier unit

Safety precautions. Nitrogen is nontoxic but can act as an asphyxiant by displacing the amount of air necessary to sustain life; for humans this is the case for more than 88 vol %. Inhalation of nitrogen in excessive concentrations can result in dizziness, nausea, vomiting, and loss of consciousness. In pure nitrogen, fainting occurs immediately without warning followed by death after a few seconds.

The rules governing the handling of liquid and pressurized nitrogen in the country of use (in Germany Technische Regeln Gase TRG 280 and 369) and safety data sheets (e.g., from Kühn Birett S023) must be complied with. Recommendations for means by which to prevent such situations are given in CGA P-14, and CGA Safety Bulletin SB-2 "Oxygen Deficient Atmospheres" (CGA: Compressed Gas Association, USA).

Liquid nitrogen is extremely cold; contact causes freezing of human tissue or burns and severe eye damage. Liquid nitrogen spills should be removed by flushing with water and airblowing. CGA P-12 gives information on safe handling of cryogenic liquids. For further information, see [54].

6. Quality Specifications and Analysis

Quality Specifications. Nitrogen produced by cryogenic air separation (see Section 4.1) usually contains less than 5 ppm of oxygen by

Table 8. Commercial grades of nitrogen

Designation	Purity, vol % (min.)	Other constituents, vol ppm (max.)				
		O_2	H_2O	C_nH_m	Ar	CO
Nitrogen 4.6	99.996	5	5	0.5	30	
Nitrogen 5.0	99.999	3	5	0.2	3	
Nitrogen, CO-free	99.999	3	5	0.2	3	0.1
Nitrogen 5.3	99.9993	2	2	0.2	3	
Nitrogen 5.6	99.9996	0.5	1	0.1	3	0.1
Nitrogen 6.0	99.9999	0.3	0.5	0.1	0.3	0.1
Nitrogen, on-site purified *		2 **	10 **	10 **		1 **
Nitrogen, liquid	99.995					

* Other specifications = $H_2 < 5$, $CO_2 < 1$ ppb by volume; particles (0.01 µm) $< 100/m^3$ (STP) [56]

volume. Argon and carbon monoxide can also be removed down to residual levels of a few ppm. The air constituents with lower boiling points than nitrogen (helium, 5.3 ppm and neon, 18 ppm) as well as the impurity hydrogen (0.5 to 0.6 ppm) from the feed air can end up in the nitrogen product, depending on the configuration of the cryogenic unit (e.g., single-column nitrogen unit, see Section 4.1).

Table 8 outlines the commercial grades of nitrogen in Germany. In the United States, the Compressed Gas Association lists nine grades of nitrogen, differentiated by oxygen content, dew point total hydrocarbon content, and other contaminant concentrations [55].

For the use in semiconductor manufacturing ultrahigh-purity nitrogen with purity 7.0 or even higher is required. To obtain such a low impurity level, on-site purification units are used (see Section 4.1).

Liquid nitrogen normally has a purity of > 99.995 vol %. Higher purities are delivered on request.

Table 9. Trace gas analyzers used in UHP nitrogen monitoring [57]

Impurity	Analytical method	Limit of detection
O_2	Hersch galvanic cell	10 ppb
H_2O	piezoelectric quartz crystal	10 ppb
CH_4	nondispersive infrared	10 ppb
CO_2	nondispersive infrared	10 ppb
H_2	gas chromatograph, reducing gas detector	10 ppb
CO	gas chromatograph, reducing gas detector	1 ppb
Particles	laser scattering	0.1 µm
Particles	Condensation nuclei	0.01 µm
O_2, H_2O, CH_4, CO_2, H_2	APIMS *	< 0.05 ppb 2.0 ppb

* Atmospheric pressure ionisation mass spectrosmetry.

Analysis. No simple qualitative reaction is known for the detection of nitrogen. Volumetric techniques or thermal conductivity measurements are suitable for the quantitative determination of N_2 in gases. Nitrogen, along with other components, can be determined with a gas chromatograph and a thermal conductivity detector; modern high-sensitivity detectors determine N_2 down to the volume ppm level. Traces of nitrogen in, e.g., helium or hydrogen are concentrated by cryogenic adsorption and analyzed in the usual manner. For impurities in ultrahigh-purity nitrogen, as required in the electronics industry, sophisticated gas-monitoring systems are used, which can monitor ppb levels of impurities continuously. Table 9 lists the analytical methods and limits of detection [57].

The Kjeldahl technique is used to determine fixed nitrogen in organic and inorganic materials. The matter is treated with concentrated sulfuric acid over various catalysts to convert nitrogen to NH_4^+. This is treated with NaOH to liberate ammonia, which is determined by titration. In the elemental analysis of organic substances, the nitrogen oxides produced by combustion are reduced to N_2, which is determined volumetrically or by thermal conductivity. Nitrogen, fixed as amino group in peptides, proteins etc. is determined after hydrolysis and ion-chromatography by colorimetric detection; normally, these analyses are conducted automatically by amino acid analyzers.

Volatile compounds containing nitrogen can be determined in a high-sensitivity gas chromatograph with a thermionic phosphorus–nitrogen (PN) detector: CN radicals are generated in a reducing flame and reduced to CN anions by an alkali bead [61]. For elucidation of the structure of nitrogen compounds by NQR, NMR, photoelectron spectroscopy, and ESCA, see [62].

7. Uses

The largest-volume use of nitrogen is for ammonia synthesis (→ Ammonia).

Metallurgy. In metallurgy, nitrogen is an alloy constituent and is used for heat treatment [63,64] and as a scavenging and protective gas.

As an alloying element in steel, nitrogen serves to improve hardness (nitriding) and corrosion resistance [65,66] (→ Steel).

In the scavenging-gas and vacuum treatment of steel melts, nitrogen is used to remove oxygen and hydrogen, and for homogenization of the melt. The scavenging gas is introduced either through lances or porous linings. The nitrogen consumption is $0.01-0.08\ m^3$ per tonne of steel, depending on the process. Nitrogen mixed with argon is employed as a blanket gas during remelting and over the casting stream and molds; it is simultaneously used for nitriding.

The consumption of a plasma remelter ranges from 0.01 to 0.05 m^3 of N_2 and 5 to 10 m^3 of Ar per tonne of steel [67]. In continuous casting, a nitrogen gas purge is maintained over the casting stream, or the stream is blanketed with liquid nitrogen delivered by an annular nozzle [68, 69]. Nitrogen is used in place of chlorine and Freons when aluminum melts are degassed to remove hydrogen and suppress oxide formation [68, 70]. Liquid nitrogen is employed for cooling the dies in extrusion systems, for quenching steels (to lower the residual austenite content), and in the fabrication of casting molds [68, 73]. Deep cryogenic treatment with liquid nitrogen at − 196 °C enhances wear resistance and hardness of tool steels [71].

Inert-Gas Shielding, Fire Fighting. Nitrogen, as an inert gas, is used to lower the oxygen concentration below the levels required to initiate or support combustion or explosion. To eliminate the risk of fire or explosion with a combustible gas, liquid or dust, the concentration of O_2 in the gas or vapor phase must be well below the explosive range of the product vapor to oxygen ratio. Table 10 lists the O_2 concentration for several reactive materials for the minimum oxygen content needed for combustion as well as the maximum recommended oxygen content that must be maintained for the inerting with nitrogen [72]. For other values and information on the pressure and temperature dependencies, see [74, 75].

Table 10. Critical and recommended oxygen contents in nitrogen for the inerting of combustible gases and dusts [72]

Flammable gas, liquid or dust	Minimum oxygen needed for combustion, vol %	Maximum recommended oxygen, vol %
Hydrogen	5	4
Methane	12	9.5
Ethane	11	8
Ethylene	10	8
Methanol	10	8
Gasoline	12	10
Coal dust	14	10
Wood dust	11	8
Sulfur	12	9
Light-metal dusts	2 – 6	0 – 2

Nitrogen atmospheres and purges are used in pipelines, vessels, and silos where flammable gas mixtures or dusts occur. An inert atmosphere can be produced by blanketing or by continuous or intermittent purging. In most cases, continous monitoring of the oxygen concentration or flammability of the atmosphere is necessary. When nitrogen blankets are used in tanks, slight overpressures are sufficient; the exhaust gas is led to a flare system [76–78].

Fires of fire class B (liquid materials, e.g., gasoline, alcohols, oils) and C (gaseous material, e.g., methane, propane, hydrogen) can be extinguished by using nitrogen. The choice of nitrogen as a fire extinguisher depends on the cost and local conditions. In firefighting in coal mines, liquid nitrogen extinguishes the fire, renders explosive atmospheres inert, and leads to cooling. Large colliery fires were combatted successfully [79].

Food Storage and Food Processing. During processing, cooling, storage, and transportation of food, liquid nitrogen or vaporized liquid nitrogen is used. Liquid nitrogen provides the cryogenic cold necessary for freezing, and nitrogen vapor as an inert medium inhibits oxygen-dependent ripening and decay processes. Further advantages of nitrogen are its sterility; the absence of taste, odor, and color; and its nontoxicity.

The flash freezing of foods with liquid nitrogen involves a shorter time than conventional deep freezing. The formation of larger ice crystals in cells and in intercellular spaces is reduced; thus, damage of cell walls is avoided. The concentration of salts, proteins, sugars and other substances in the cell liquor therefore does not increase and so there is less water diffusion driven by osmotic pressure difference across the cellwalls. With increasing freezing velocity the drip loss of cellular liquor during thawing of the product is diminished.

Tunnel, spiral, or cabinet freezers are usually employed in cryogenic food freezing. High-speed freezing in immersion freezers is used in special cases only. Figure 17 shows the various freezer types. In the tunnel freezer, the product is precooled in countercurrent against vaporized nitrogen, then exposed to a liquid spray. The capacity of tunnel freezers varies from 0.5 to 3 t/h of frozen product. Figure 18 shows an in-line tunnel freezer during loading. In the spiral freezer, the product moves along a spiral belt through the annular nitrogen spray. Cryogenic

Figure 17. Schematics of the various freezer types (Linde Cryoline system)

flash-freezing requires ca. 0.8 – 1.2 kg liquid nitrogen per kilogram of product [73, 80, 81].

Goods in transit can be kept cold with liquid nitrogen instead of refrigerating equipment. A controlled quantity of liquid nitrogen is sprayed into the cargo space or vaporized from an open vessel whose insulation is adapted to the desired vaporization rate.

Food is stored under controlled atmospheres or in cold-storage houses. In controlled atmospheres (CA), the oxygen and carbon dioxide contents are usually kept at 3 – 4 vol % and max. 2 vol %, respectively, at a high relative humidity and low temperature. Thus, ripening of fruits and vegetables can be postponed until sale without appreccable quality degradation. Nitrogen can be provided by noncryogenic processes or from liquid nitrogen, which is advantageous because of its low temperature.

Figure 18. An in-line tunnel freezer in operation (Linde Cryoline)

Modified atmospheres are special gas mixtures rich in nitrogen and are increasingly used in the packaging of foods (modified atmosphere packing, MAP). Quality, texture and appearance are greatly influenced by the absence of oxygen.

In cold-storage depots a temperature of – 24 °C must be maintained. In the case of power loss or failure of the refrigeration system, liquid nitrogen can be utilized for emergency cooling. Often, liquid-nitrogen emergency cooling manifolds are installed [82].

Nitrogen is increasingly used in the brewing and soft-drinks industries. Excess oxygen is removed from brewery liquors and beer by stripping with nitrogen. Sparge deoxygenation typically reduces the oxygen content from 10 ppm to 0.1 ppm. Nitrogen serves as an inert gas for canning and bottling lines [83]. Noncarbonated beverages are pressurized during canning by injection of a small amount of liquid nitrogen so that traditional methods of packing, stacking, and shipping can be used without the presence of CO_2 [84].

Manufacturing Applications. In the plastics industry, liquid nitrogen is used for flash removal, size reduction, shrink-fitting, and extrusion blow molding. High-purity nitrogen is used extensively throughout the electronics industry.

Flash Removal. Flash must be removed from molded plastic parts. Brief cooling with liquid nitrogen renders the flash brittle while leaving the part still flexible. The result is a weak point at the transition from flash to part, so that the flash can easily be removed in a tumbler or a vibration or blasting machine (e.g., MSA and TSA flash removal, Linde, Höllriegelskreuth) [85, 86]. The consumption rate is ca. 0.2 – 1.5 kg of liquid nitrogen per kilogram of plastic.

Cryogenic Grinding and Disintegration. Embrittlement of grinding feed with liquid nitrogen makes it possible to handle adherent, soft, or tough materials. In addition to better grindability, the advantages include easier heat removal during grinding and the prevention of dust explosions by the inert atmosphere generated. Also the possibility of efficient separation is provided in cases in which some materials in a mixture become brittle, while others do not. Cryogenic grinding or cryopulverizing is employed for plastics, rubber, spices, coffee, cocoa, soybeans, waxes, etc. The method is also useful in processing pharmaceutical products that have low softening points or are heat sensitive [87]. Cryogenic disintegration or debonding is used during recycle operations, e.g., reclaiming rubber from used tires, separation of ferrous and nonferrous scrap, stripping polymeric insulation from cables, and for recycling also for batteries, electronic scrap, composite materials, and color concentrates [88–90].

Figure 19 (see next page) shows a schematic of a cryogenic grinding system, in which a cold stream of nitrogen is led in cocurrent to the grinding feed. The temperature of the cooling screw or tunnel is controlled by the injection of liquid nitrogen and is adapted to the feed material (e.g., ca. – 30 °C for spices but – 160 °C for

nylon). The consumption of a cryogenic grinding unitis 0.5 – 1.5 kg of liquid nitrogen per kilogram plastic or 0.25 kg/kg for spices; that of a disintegrator for old tires 0.5 kg per kilogram of rubber processed [91].

Shrink-Fitting. When parts are assembled with shrink fits, the inner part is immersed in liquid nitrogen so that its volume is reduced. Then it is inserted in the outer part. The heating of the inner part leads to a press fit between the parts. When cryogenic shrink-fitting is used instead of heating the outer part, metallurgical changes are avoided. Cryogenic shrink-fitting requires ca. 0.35 (brass) to 0.80 (aluminum) kg of liquid nitrogen per kilogram [114].

a) Star feeder for feed and product; b) Cooling screw; c) Impact grinder; d) Product bin; e) Dust-removal filter; f) Recirculation blower; g) Liquid nitrogen regulating valve; h) Waste nitrogen throttle valve

Extrusion Blow Molding. Hollow plastic bodies are made by extruding the soft plastic into a hollow mold in an extrusion machine, then allowing the material to cool in the mold. The working fluid is compressed air. If liquid nitrogen is used instead of compressed air, the cycle time on the extruder can be greatly reduced. The nitrogen is injected into the hollow mold in liquid form. The pressure generated as it vaporizes forces the plastic against the mold and cools it. The use of nitrogen diminishes the tendency to stress cracking and enhances the transparency of PVC moldings. Nitrogen-assisted injection molding also results in significant weight savings in structural plastic components. The consumption is 0.1 – 0.8 kg of liquid nitrogen per kilogram of plastic [92, 93].

In the plastics industry the cold of liquid nitrogen is also used in the fabrication of high-pressure rubber hoses and for easy polishing of plastic car parts (cold polishing). Liquid nitrogen also acts as a propellant for foaming plastics.

Electronics Manufacturing. Nitrogen is used extensively throughout the electronics industry and in semiconductor production. Blanketing by standard pure nitrogen atmosphere is advantageous during soldering of electronic parts by wave-soldering processes [94] and infrared reflow soldering [95].

High-purity or ultrahigh-purity nitrogen is used in the semiconductor and chip-manufacturing industry as a blanketing medium and as an inert gas carrier for reactive process gases in chemical vapor deposition and doping processes.

Oil and Gas Recovery. High-pressure nitrogen (up to 600 bar) is used in many working processes in oil and gas drilling. For well-completion drilling, nitrogen gas is used as a drilling medium in under-pressured reservoirs. When hydrocarbon zones are passed, nitrogen minimizes the risk of downhole fires. Other effects of nitrogen are to create aerated nonflammable drilling fluids, removing liquids from the feed drill, perforating casings, and breaking up deposit materials. When liquid nitrogen is used, special high-pressure vaporisation units are required. Costly cryogenic equipment is being replaced by on-site membrane systems [96].

Nitrogen injection for enhanced oil and gas recovery has become an efficient method for oil reservoirs under initial conditions or for those depleted by water or steam flooding [97]. Nitrogen has advantages over CO_2 because of is lower solubility in water and hydrocarbons. Nitrogen for enhanced oil recovery is produced cryogenically. A typical large reservoir may require up to 100 000 m^3/h (STP) at a pressure of 41 MPa. The air separation plants at the field site are modified to produce large quantities with improved efficiency [98] (see Chapter 4.1).

Cryomedical and Cryobiological Applications. Liquid nitrogen freezing has many applications in medicine and biology. Cryogenic treatment with liquid nitrogen allows the preservation of stored blood past the maximum four-week life of conventional units. Before deep-freezing, the plasma is separated and a stabilizer (e.g., glycerol or dimethyl sulfoxide) is added to reduce osmotic damage. After immersion in liquid nitrogen, the frozen unit of blood is stored below $-110\,^{\circ}C$ in a cold N_2 gas atmosphere over liquid nitrogen. The technique gives erythrocyte survival rates in excess of 98 % [99]. Deep-freezing with liquid nitrogen also helps to preserve bone marrow, skin tissue, corneas and human sperm.

Cryosurgery is an alternative to excision surgery and is useful in the treatment of hypertrophic and malign neoplasms. Liquid nitrogen is applied by cryoprobes or cryospray. Ice balls are generated within the area to be distroyed, whereas freeze spraying is an effective way of freezing large tumors. Further clinical applications are in oral surgery, ophthalmology and rheumatism treatment. A survey is given in [100].

For preserving biological substrates, ready-made systems are available for yeast, bacteria, or proteins. For this purpose liquid nitrogen is sterilized by steril-filtration. So-called cryobanks are operated for the storage of blood conserves, livestock semen for cattle breeding, preserving environmental samples for documentation, etc. [101]. The digestion of cells and microorganisms containing active enzymes or heat-sensitive proteins can be carried out by cryogenic freeze cleaving. After immersion into liquid nitrogen, pellets of the material are formed. By cryogrinding, purification, and drying the active substances (i.e., enzymes or related biologically active material) are recovered. The yield of active substance is increased by 50 % compared to conventional digestion [102].

Other uses. Gaseous or liquid nitrogen is also used for various applications:

Ground Freezing. Freezing of water contained in unstable ground temporarily improves the strength and eliminates or reduces water movement. Ground freezing is used for making vertical shafts, sewerage, subway tunnels, etc. [103, 104]. *Pipe freezing* generates temporary plugs in pipelines to allow local cutting or repairs [105]. The recovery of tar and oil spills from contaminated soils is facilitated by freezing and embrittlement.

Cryocondensation. Waste-gas streams containing organic or chloro-organic impurities can be purified by indirect condensation of the compounds using cryogenic cold. Thus, 99 % purification can be achieved by countercurrent cooling with liquid nitrogen; final purification can be performed cold adsorption on molecular sieve adsorbers. Regeneration of the adsorbers together with the condensate from cooling yields a liquid containing 99.9 % of the impurities [106].

Tire Curing. In the tire manufacturing process, nitrogen together with steam is used to create heat and pressure required for proper vulcanization ("curing") of the tire rubber in a press mold. The curing step shapes the tire into its final form; the tire mold is fitted with a collapsible rubber bladder into which the curing media are injected. The use of oxygen-free nitrogen is advised to increase the bladder life which is a critical factor in tire curing [107].

Concrete Cooling. Concrete hardening is an exothermic process, and the large amounts of heat produced in the concrete body can cause cracking. With large concrete volumes, high quality demands on the concrete, or in hot climates, cooling with liquid nitrogen is recommended. This can be done either by precooling the water, aggregate, and cement or by directly cooling the concrete mixture by injecting liquid nitrogen [108].

Chemical Industry. In the chemical and petrochemical industry, nitrogen is used for simultaneous blanketing and cooling of reactors. Cooling times and thus idle times in, for example, hydrogenation or reforming reactors can be shortened by the injection of liquid nitrogen. Nitrogen also ensures safe operation due to its inertness [109]. The cold of liquid nitrogen is used to control or to stop chemical reactions. For example, exothermic polycondensations can be terminated by quenching the product resin in liquid nitrogen [110]. An alternative to removing coke from thermal reactor tubes by decoking with air is the Sandjet process. A blasting material is blown down the reactor pipes at high speed using nitrogen as carrier gas. Coke deposits are removed quickly and without emissions to the atmosphere. Corrosion products can be removed

by using sharp-edged cinders as blasting material [111].

There are many other applications for which nitrogen can be used; they include:

1) Filling high-performance shock absorbers or pneumatic spring suspensions to avoid oxidation and degradation of the filling oil.
2) Conditioning of natural gas to sales gas specifications from LNG storage facilities by adding nitrogen (i.e., to adjust the heating value) before compression and pipeline distribution [112].
3) The liquid nitrogen wash process used to purify hydrogen, produced from crude oil or coal, for use in ammonia synthesis (→ Gas Production, Chap. 5.6.3.).

8. Economic Aspects

In Europe nitrogen is the second most important industrial gas after oxygen. Total captive and merchant nitrogen production in 1996 amounted to $8.5 \times 10^9\,m^3$ (STP) in Germany and to $21.5 \times 10^9\,m^3$ (STP) in Europe. An annual growth of ca. 5 % per annum is expected up to the year 2001. In the United States about $22 \times 10^9\,m^3$ (STP) of nitrogen was produced in 1992, and this rose to $28.3 \times 10^9\,m^3$ (STP) in 1996. Production in Japan in 1996 was $9.8 \times 10^9\,m^3$ (STP), approximately 40 % of which was gaseous or liquid merchant nitrogen.

Gaseous nitrogen production is growing more rapidly than liquid nitrogen production for two reasons: First, the largest applications have always been most economically served by gas from multi-user or over-the-fence pipelines. Second, noncryogenic production technologies such as membranes and PSA are making gas production at customer sites economic under more and more circumstances [113].

1. Introduction

Since 1941, industrial nitrogen fixation has been carried out almost entirely by the Haber process (→ Ammonia). The Norwegian arc process was last exploited commercially at that time, and other processes, such as the cyanamide process, ceased to be significant even earlier. Apart from various minor efforts to revive the arc process to operate under rather special, restricted circumstances (see Chap. 11), hopes for new nitrogen-fixation processes have stemmed from the observation that biological nitrogen fixation takes place under mild conditions in the presence of dioxygen and water, and that it should therefore be possible to reproduce such processes in a completely synthetic system in vitro. The requirement for molybdenum or vanadium first demonstrated in the 1930s also supported the belief that the biological processes involve metalloenzymes [1]. This prompted research, successful first in 1965, into the synthesis of dinitrogen complexes [2]. The two related but different areas of research, biological and chemical, have been the subject of increasing effort since ca. 1960. The first indications of application of this research to industrial nitrogen-fixation processes are only now becoming evident.

Some of the material discussed here is also dealt with briefly in an earlier article, see → Ammonia, Chap. 4.7.

2. Biological Nitrogen Fixation

2.1. Microorganisms

All known biological nitrogen-fixation processes are performed by microorganisms. Some, such as the rhizobia, fix nitrogen in obligate symbiotic relationship with plants, principally but not exclusively with legumes, but other non-obligate symbioses–for example, *Azotobacter paspalum* with a tropical grass–seem to occur accidentally. The basis of the symbiosis appears to be the exchange of carbohydrate for fixed nitrogen. Other, non-symbiotic systems include

10.1002/14356007.a17_471

anaerobic and aerobic bacteria (e.g., *Clostridium pasteurianum* and *Azotobacter vinelandii*, respectively), blue-green algae or cyanobacteria (e.g., *Anabaena cylindrica*), and phototrophic bacteria (e.g., *Rhodospirillum rubrum*).

In certain parts of the world, nitrogen-fixing organisms living on the leaves of the water fern azolla have been used as a "green fertilizer," for example, by ploughing the ferns into the soil. However, the aim of recent research is the construction of nitrogen-fixing plants by incorporation of appropriate bacterial DNA into the plant genome rather than the exploitation of natural nitrogen-fixing systems [3].

2.2. Nitrogenases

It is recognized that there are at least three varieties of nitrogenase, possibly all expressed in nature under appropriate conditions [4]. Until recently, the existence of only a molybdenum-containing nitrogenase was recognized, but this may be a consequence of artificial selection forced by culture conditions rather than an expression of the state of affairs in nature. All molybdenum nitrogenases are very similar, whatever their source. The recognized vanadium nitrogenases are very similar to the molybdenum nitrogenases [5], but the third nitrogenase seems to differ in some respects because its component proteins do not form active hybrid nitrogenases with proteins from the other two nitrogenases [6].

The molybdenum nitrogenases consist of two air-sensitive metalloproteins. The oxygen sensitivity means that organisms which use nitrogenases have developed techniques to separate nitrogen fixation either temporally or spatially from activities that involve oxygen, e.g., photosynthesis and respiration. The larger protein (the molybdenum – iron protein) contains 2 molybdenum atoms, ca. 25 iron atoms, and an equivalent amount of "inorganic" sulfide and has a molecular mass of ca. 230 000. Because the protein comprises four subunits, two each of two kinds, its constitution is designated $\alpha_2\beta_2$. An iron – molybdenum cofactor (FeMoco), which contains no peptide residues and has inorganic constituents with approximate stoichiometry Fe_6MoS_4, has been extracted from this protein. Some of the iron atoms are apparently contained in Fe_4S_4 clusters. The smaller, iron protein (M_r ca. 60 000) has two subunits (δ_2), and contains four iron atoms in a single Fe_4S_4 cluster [3].

The vanadium nitrogenase is in most respects similar except that vanadium replaces molybdenum; it possesses an iron – vanadium cofactor, FeVaco.

2.3. Reaction Stoichiometry and Mechanism

To obtain fixation in vitro, the two proteins are mixed, generally with considerable excess of the smaller, together with a reducing agent (normally sodium dithionite), adenosine 5′-triphosphate (ATP, an energy source), a buffer, and dinitrogen (nitrogenase reduces many substrates, most notably acetylene; for details, see [3]). The ability to reduce acetylene to ethylene has long been regarded as characteristic of nitrogen-fixers, and it has even been used diagnostically because of the relative ease of testing for it. The reduction of dinitrogen to ammonia by a molybdenum nitrogenase is believed to be most efficient in use of electrons when its stoichiometry corresponds to the reaction

$$N_2 + 8\,H^+ + 16\,ATP + 8\,e^- \longrightarrow 2\,NH_3 + H_2 + 16\,ADP + P^i$$

where P^i represents inorganic phosphate [3].

Evolution of dihydrogen always occurs and, at its minimum, represents 25 % of the electron flux. The evolution of dihydrogen is believed to be associated with its displacement by dinitrogen at a polyhydridic metal site, presumably molybdenum. Although precedents for this kind of displacement exist, it is not clear why nitrogenase should adopt it.

$$[CoH_3(PPh_3)_3] + N_2 \rightleftharpoons [CoH(N_2)(PPh_3)_3] + H_2$$

The stoichiometry of dinitrogen reduction by vanadium nitrogenase suggests that 50 % of the electron flux is used in dihydrogen evolution. If this is a minimum loss of electrons, a very different mechanism is indicated for vanadium-mediated reduction compared to molybdenum-mediated reduction.

The pre-steady-state kinetics of dinitrogen reduction by *Klebsiella pneumoniae* wild-type

Figure 1. Simplified scheme for the function of nitrogenase
$E_0, \ldots, E_n$ represent different states of the enzyme system, each arising as one electron (of the total of eight electrons for the complete cycle) is taken up. For each state, the intermediate metal species or the reaction believed to occur is indicated. These are inferred from chemical studies.

nitrogenase have been studied by stopped-flow spectrophotometry, and the mechanistic scheme in Figure 1 has been proposed to accommodate the data [7]. In Figure 1, E_0, E_1, ..., E_7 represent eight different states of the enzyme system corresponding to the eight individual electron transfers of the stoichiometric reaction described above. For the transfer of a single electron ($E_n \rightarrow \mathrm{E}_{n+1}$), the smaller, iron protein is believed to accept an electron from the reducing agent and then form a "complex" with the larger protein, to which it transfers the electron, and from which it finally dissociates before accepting another electron. Dinitrogen binds to the larger protein, and accepts electrons stepwise while simultaneously taking up protons from solution. The proposed identity of the dinitrogen or hydride species involved in each stage is indicated in Figure 1; further details are given in [8,9]. None of this analysis can reveal the dinitrogen pattern of reactivity at an atomic level, which requires detailed chemical studies.

2.4. Genetic Control of Nitrogenases

The successful expression of bacterial nitrogen fixation activity in a plant would seem to require a good understanding of the bacterial genome. The 20 or so genes required for the synthesis, control, and function of the molybdenum nitrogenase in *Klebsiella pneumoniae* are shown in Figure 2; they are contiguous and are found in a single cluster. In the azotobacters, in contrast, the genes are scattered throughout the chromosome, with gaps of as in 1984 unidentified function [10]. Azotobacter chromosomes also contain apparently duplicate genes which are concerned with the vanadium and third nitrogenases [11]. There are also some additional regulatory genes, and in the rhizobia, for example, genes concerned with infection. However, there seems a remarkable degree of conservation between genes fulfilling the same function, whatever their origin.

Figure 2. The linear arrangement of the nif gene cluster of *Klebsiella pneumoniae*
The letters Q, B, A, L, etc. are internationally agreed gene designations and have no further significance. The proposed functions of the gene products are shown in the right-hand column.

Attempts are being made to express the products of some of these genes, such as nifH, in plant chloroplasts as a preliminary to attempting the transfer and expression of the whole genome. Success in this endeavor would be a great technical achievement. Its value in agricultural terms, however, would remain to be proven.

3. Reactions of Dinitrogen

3.1. Reaction with Metals and Metal Complexes

Dinitrogen interacts with most transition elements, but the intensity of interaction varies between the extremes of weak physisorption (detectable only under very specific conditions) to strong chemical interaction resulting in strong metal – nitrogen binding and breaking of the N – N bond, i.e., nitride formation; Figure 3 summarizes the reactions. A rough division, indicated by the stepped line, can be made between the strong interactions resulting in nitride formation and weak interactions which allow the dinitrogen molecule to remain intact. In contrast, dinitrogen complexes stable at room temperature are formed by almost all transition elements, given an appropriate arrangement of co-ligands (Fig. 4).

3.2. Activation of Dinitrogen for Ammonia Formation

A major emphasis in nitrogen fixation research has been to find conditions under which coordinated dinitrogen can be converted to ammonia. However, strongly reduced systems (analogous to the nitride-forming metals) also exist which, under anhydrous conditions, can apparently reduce and even split dinitrogen molecules. Addition of protons then yields ammonia directly. In addition, there is a third major area of fixation research in which conversion of dinitrogen to ammonia is observed. These have been referred to as "soups," and the involvement of dinitrogen complexes is inferred from kinetic and spectral measurements (see Chaps. 7 and 8).

Figure 3. Room temperature adsorption behaviour of dinitrogen on various metals
Symbols doubly underlined indicate exothermic nitrides; singly underlined indicate endothermic nitrides. The thick line is the borderline between dissociative and molecular adsorption at room temperature.
U = Binary nitride unknown; M = molecular adsorption; D = dissociative adsorption; (D) = probable dissociative adsorption

3.3. Structures of Dinitrogen Complexes

Considerable structural variety exists among dinitrogen complexes [8, 9]. The largest group of dinitrogen complexes contains one, occasionally two, and, in one case, three dinitrogen molecules bound linearly end-on to a metal atom, with a nitrogen – nitrogen separation of ca. 112 pm, little longer than in free dinitrogen. Some of these complexes, generally those of transition elements of groups 4, 5, and 6, can be converted to ammonia and/or hydrazine by the action of protic acids. However, dinitrogen complexes with elements of groups 7 – 10 have similar geometries and dimensions, but little or no tendency to undergo protonation. Clearly, geometry is no criterion of activation.

Figure 4. Binding and activation of coordinated dinitrogen
[a] Terminal, end-bound N_2, activated to protonation, yielding ammonia and/or hydrazine.
[b] Bridging, end-bound N_2, activated to protonation, yielding hydrazine. In some cases, it is not clear whether end-on or side-on dinitrogen (or both) is activated.
[c] Side-on N_2 activated to protonation, yielding hydrazine (observed for a single Sm complex).
[d] Other activated N_2; in these systems additional reductant is required.
[e] Terminal end-bound N_2, activated to alkylation and acetylation, yielding diazenido complex.
[f] All the elements shown in this figure form dinitrogen complexes stable at 20 °C except for these, for which stable dinitrogen complexes have not yet been unequivocally characterized.
[g] Acetylation of coordinated N_2 observed.

These complexes contain dinitrogen that can function as a base and is polarized in the sense $M-N^{\delta+}-N^{\delta-}$. As Lewis bases they form adducts with Lewis acids (including, often, a proton). Such bridging dinitrogen adducts rarely contain activated dinitrogen. In a second group of complexes containing bridging dinitrogen, bond length considerations imply that the dinitrogen may be formally regarded as $(N{=}N)^{2-}$ or even $(N-N)^{4-}$. Electron counting generally leans towards the latter formulation. These complexes are generally homonuclear and contain transition elements of groups 5 and 6. They react with proton acids to yield hydrazine, consistent with the presumptive reduced nature of the dinitrogen. As routes from molecular dinitrogen to hydrazine, they are, however, not very promising, since syntheses directly from molecular nitrogen generally give low yields, and alternative syntheses based on sources of fixed nitrogen are recommended for most purposes.

A number of other structural types of dinitrogen complex exist. These are often uncommon, single examples and are not discussed here. For a general review, see [8, 9].

4. Protonation and Alkylation of Dinitrogen Complexes

4.1. End-on Dinitrogen Complexes

Although reactions of dinitrogen have been known for many years, such reactions have involved extreme conditions or highly reduced chemical species that are generally unstable in the presence of water.

The first dinitrogen complex, $[Ru(NH_3)_5(N_2)]^{2+}$, was reported in 1965 [2]. Though unreactive toward protonation, it opened the way to synthesis of many other dinitrogen complexes.

Protonation Reactions. The first reported protonation of a dinitrogen complex was of $[W(N_2)_2(dppe)_2]$ to form $[WBr(NNH_2)(dppe)_2]^+$ ($dppe = Ph_2PCH_2CH_2PPh_2$) [12]. Shortly afterwards, it was shown that complexes of the type $[M(N_2)_2P_4]$ (M = Mo or W; P = tertiary phosphine) can be protonated directly to ammonia when P is a tertiary monophosphine [13, 14].

The highest yield of ammonia (90 % based upon $W^0 \rightarrow W^{VI}$) is obtained from *cis*-$[W(N_2)_2(PMe_2Ph)_4]$ and sulfuric acid in methanol at room temperature. One mole of dinitrogen is evolved rapidly, together with a trace of dihydrogen, while the second mole of dinitrogen yields ammonia and a small quantity of hydrazine. Typical data are listed in Table 1. The reasons for the wide variation in the amounts of products are not known. Hydrazido(2−) (NNH_2^{2-}) species have been isolated from many of these systems, and hydrazidium(1−) (NNH_3^-) complexes have also been characterized [15].

Table 1. Yields of ammonia and hydrazine from the reaction of $[M(N_2)_2P_4]$ ($P = PMe_2Ph$ or $PMePh_2$) with sulfuric acid at room temperature [14]

Complex	Solvent	NH_3, % [a]	N_2H_4, % [a]	N_2, % [b]
cis-$[W(N_2)_2(PMe_2Ph)_4]$	MeOH	90	2	94
cis-$[W(N_2)_2(PMe_2Ph)_4]$	THF	46	13	59
trans-$[W(N_2)_2(PMePh_2)_4]$	THF	36	15	54
cis-$[Mo(N_2)_2(PMe_2Ph)_4]$	MeOH	36	< 1	40
cis-$[Mo(N_2)_2(PMe_2Ph)_4]$	THF	35	< 1	34
trans-$[Mo(N_2)_2(PMePh_2)_4]$	THF	4	< 1	ca. 5

[a] Based upon six electrons available from each metal atom.
[b] Based upon one dinitrogen molecule expected from each metal atom.

Stepwise protonation of coordinated dinitrogen, as shown below, has been proposed as a basis for understanding these reactions.

Although all the species **1**–**6** have been characterized, only **1**–**4** have been isolated from protonation reactions. For discussion of protonation mechanisms, see Chapter 5.

It is likely that a similar mechanism holds for the protonation of dinitrogen in $[Mo(N_2)_2(triphos)(PPh_3)]$ ($triphos = Ph_2PCH_2CH_2PPhCH_2CH_2PPh_2$), at least in the initial stages. The final stages may well involve a disproportionation [16].

$$2\ \textit{trans}\text{-}[Mo(N_2)_2(triphos)(PPh_3)] \xrightarrow{4\,HBr} 2\,N_2 + 2[MoBr(NNH_2)(triphos)(PPh_3)]Br$$
$$\xrightarrow{4\,HBr} 2[MoBr_3(triphos)] + 2[PPh_3H]Br + N_2 + 2\,NH_3$$

Table 2. Production of ammonia by an electrochemical cycle [20] ∗

Complex	Amount of complex, µmol	Amount of NH_3, µmol	Yield of NH_3, mol % per mole of complex
$[W(NNH_2)(O_3SC_6H_4Me)(dppe)_2]^+$	145	33	23
$[W(NNH_2)(O_3SC_6H_4Me)(dppe)_2]^+$	341	99	29

∗ Conditions: 0.2 mol/dm^3 $[NBu^{n4}][BF_4]$ in THF (30 cm^3); Hg pool cathode at − 2.6 V vs. ferrocinium/ferrocene; cathode compartment purged with N_2.

Figure 5. Cyclic electrochemical systems for producing ammonia, amines, and hydrazines [$\underline{M}$ = M(dppe)$_2$, M = Mo or W, R = alkyl] [20]
(A) X = Br or I; (B) X = 4-$CH_3C_6H_4SO_3$

Alkylation Reactions. Dinitrogen in $[M(N_2)_2(diphosphine)_2]$ can also be alkylated and silylated in high yields. Alkylation reactions (for mechanism, see Chap. 5) yield products that formally resemble the protonated species M−NNH and M=NNH_2 discussed above [17]. Typical examples are $[MoBr(NNMe)(dppe)_2]$ and $[WBr(NNMe_2)(dppe)_2]Br$. Such compounds can be destructively reduced (for example, by lithium aluminum hydride) to give the corresponding amine and ammonia [18].

Cyclic Electrochemical Systems. More interesting is the controlled two-electron chemical or electrochemical reduction of the dialkylhydrazide to yield, for example $[W(NNMe_2)(dppe)_2]$ [19]. Treatment of these species with acid results in the cleavage of the N−N bond, as shown in Figure 5 A. Normally, electrochemical reduction of the NNH_2^{2-} analogues of the alkylhydrazides yields dihydrogen, but in the specific case when X is 4-$CH_3C_6H_4SO_3$ the system undergoes reduction in a manner similar to the alkylated systems (Fig. 5 B) and thus constitutes a cyclic system to generate ammonia from dinitrogen. Typical data are given in Table 2.

4.2. Bridging Dinitrogen Complexes

Much less information is available on protonation of dinitrogen-bridged compounds. Complexes containing formal N_2^{2-} or N_2^{4-} (e.g., $[\{Ta(CHBu^t)(CH_2Bu^t)(PMe_3)_2\}_2N_2]$) give hydrazine in high yield on treatment with protic acids [21]. The N−N bond length here is ca. 120 pm, intermediate between a triple and a single bond. However, $[\{Zr(C_5Me_5)_2N_2\}_2N_2]$ also yields hydrazine and (with HCl) $[Zr(C_5Me_5)_2Cl_2]$, although the N−N bond length is only 118.2 pm [22]. In the latter case, poorly understood bridging – terminal dinitrogen exchange reactions occur and the system requires further research.

Figure 6. Mechanism of protonation of coordinated dinitrogen in complexes $[M(N_2)_2(\text{diphosphine})_2]$ by acids HX (X = Cl or Br) in tetrahydrofuran [24]

Figure 7. Mechanism of protonation of *cis*-$[M(N_2)_2(PMe_2Ph)_4]$ (M = Mo or W) by acids HX (X = Cl, Br, or HSO_4^-) in methanol [25]

Figure 8. Mechanism of protonation of bridging dinitrogen in $[\{M(S_2CNEt_2)_3\}_2N_2]$ (M = Nb or Ta) by acids HX (X = Cl or Br) in acetonitrile [26]

Protonation of Complexes Yielding Ammonia. Many of the less common and highly reduced dinitrogen complexes containing bridging or side-on dinitrogen also protonate at dinitrogen. For example, protonation of $[\mu_3\text{-}N_2\{(\eta^5,\eta^5\text{-}C_{10}H_8)(\eta^5\text{-}C_5H_5)_2Ti_2\}\{(\eta^1,\eta^5\text{-}C_5H_4)(\eta^5\text{-}C_5H_5)_3Ti_2\}]\cdot[(\eta^5\text{-}C_5H_5)_2Ti(C_6H_4O_3)]$, which has an N–N bond length of 130.1 (12) pm, in aqueous ether gives ammonia (> 90 % yield) and some hydrazine [23].

5. Mechanisms of Reactions of Coordinated Dinitrogen

Protonation Reactions. The mechanisms of protonation and alkylation of coordinated dinitrogen have been investigated in detail, principally by kinetic studies. The reaction schemes outlined in Figures 6 and 7 summarize the conclusions and refer generally to the reactions discussed in Chapter 4. The reader is referred to the original publications for more details of the methods and of the analysis [24–27]. The actual route taken in any given case depends on the diphosphine, the acid, and the solvent. Although these reactions stop normally at the hydrazide(2−) (NNH_2^{2-}) stage, NNH_3^- has also been recognized in two cases.

The protonation of dinitrogen complexes with at least one tertiary monophosphine as ligand can yield ammonia. Only the initial stages have been kinetically established (Fig. 6). The solvent is an integral part of this mechanism, although this may not be evident in the final products.

The sole kinetic study on the protonation of bridging dinitrogen involve a species containing a "reduced" form of dinitrogen (Fig. 8).

Alkylation Reactions. Alkylation reactions of dinitrogen complexes have not been success-

Figure 9. Alkylation of coordinated dinitrogen in $[M(N_2)_2(\text{diphosphine})_2]$ (M = Mo or W) by alkyl halides RX (X = Br or I) in various solvents (SH) [8,27]

Figure 10. Protonation of the five-coordinate hydrazide species $[Mo(NNR_2)(dppe)_2]$ by HBr in acetonitrile [27]

Figure 11. Proposed scheme for the catalytic nitridation of aluminum (X = Cl, Br, or OBu) [31]

ful when the ligands are all tertiary monophosphines. The free-radical scheme (Fig. 9) applies to complexes with two tertiary diphosphines and is the only mechanistic scheme that is pertinent, with the possible exception of two examples: one of nucleophilic attack and one of electrophilic attack on coordinated dinitrogen. The reactions with alkyl halides that convert the diazenide (NNR^-) to hydrazide (NNR_2^-) probably involve nucleophilic attack (S_N2) of the exo-nitrogen on the α-carbon atom of the alkyl group.

Splitting of the N−N bond has been studied kinetically only in the case of dialkylhydrazide complexes, though essentially the same mechanism is believed to hold in the case of the species involved in the electrochemical cycle (see Section 4.1) (Fig. 10). The intermediacy of the hydrazidium ($NNHR_2^-$) species is particularly noteworthy, because it may prove to be a general feature of N−N bond-breaking mechanisms [27].

The arylation of coordinated dinitrogen to give an aryldiazenido complex is restricted at present to a single example [28].

6. Fixing Systems Involving Chemical Reduction of Dinitrogen Before N−H Bond Formation

6.1. Nitriding Systems

Typically, these nitrogen-fixing systems consist of a transition metal compound that binds and reduces dinitrogen, along with a strong reducing agent. They are normally oxygen- and water-sensitive, and release ammonia and/or hydrazine upon addition of acids or protic solvents. Work in this area was stimulated by Vol'pin, whose publication in 1964 was the forerunner of all modern work on nitrogen fixation [29]. His initial systems were $CrCl_3/LiAlH_4/N_2$ at 15 MPa, which gave 0.02 mol of ammonia per mole of $CrCl_3$, and $CrCl_3/EtMgBr/N_2$ at 15 MPa, which gave 0.17 mol of ammonia per mole of $CrCl_3$. Since then, many metal halides have been used, some of which yield appreciable quantities of dinitrogen at even 101.3 kPa nitrogen pressure. Typical data for such systems, often referred to, perhaps inaccurately, as nitriding systems, are presented

Table 3. Fixation of nitrogen by typical nitriding systems [30]

System	Molar ratio of complex to reductant	Solvent	N_2 Pressure, MPa	Reaction time, h	Yield of NH_3, mol/mol complex
$[Ti(C_5H_5)_2Cl_2]$/EtMgBr	9	Et_2O	15	31	0.93
$[Ti(C_5H_5)_2Cl_2]$/Li(Hg)	10	THF	0.1	72	0.70
$[Ti(C_5H_5)_2Cl_2]$/Li($C_{10}H_8$)	6	THF	0.1	16	0.96
$[Ti(C_5H_5)Cl_3]$/Mg	2	THF	0.1	24	0.46
$TiCl_4$/Na	excess	THF	0.1	144	0.44
$CrCl_3$/Pr^nMgBr	9	Et_2O	15	11	0.30
$MoCl_5$/$LiAlH_4$	9	Et_2O	15	12	3.03
WCl_6/EtMgBr	9	Et_2O	15	11	0.15
$FeCl_3$/Mg,MgI_2	14 : 2.5	$Et_2O-C_6H_6$	8 – 10	7	0.26
$[VO(acac)_2]$/$LiBu^n$	9	$n-C_7H_{16}$	7.5	10	0.32
$Ti(OPr^i)_4$/Na($C_{10}H_8$)		THF	0.1	0.5	1.3

in Table 3 [30]. An electric current can also be used as a reducing agent [31].

Although the necessary final hydrolysis destroys a nitriding system and renders it noncyclable, the catalytic nitridation of aluminum has been achieved with a mixture of a titanium(IV) compound, aluminum, and aluminum tribromide in benzene (see Fig. 11 and Table 3) [30]. Hydrolysis of the resultant product releases ammonia (Table 4).

Table 4. Yields of ammonia via catalytic nitridation of aluminum in the system $TiCl_4$/Al/$AlBr_3$, $p_{N_2} \approx 10$ MPa [31]

Molar ratio $TiCl_4$: Al : $AlBr_3$	Reaction time, h	NH_3, mol per atom of Ti	NH_3, % *
1 : 12 : 33	14	11	92
1 : 150 : 200	30	95	64
1 : 600 : 1000	30	286	48

* With respect to reducing agent.

The mechanisms of such reactions have not yet been elucidated in detail. Nevertheless, some indication of what occurs may be given by the characterized reaction products in the nickel – dinitrogen – phenyllithium [32] and cobalt – dinitrogen – potassium systems [33]. In these systems, which yield hydrazine and/or ammonia on hydrolysis, the dinitrogen is bound in a complicated end-on/side-on fashion by both kinds of metal atom; however, no nitrides have been detected.

6.2. Cyclopentadienyltitanium Systems

The most studied systems are those based upon cyclopentadienyltitanium compounds, although even here the reactions are not well understood. Several dinitrogen complexes in this series are known. Compounds $[\{Ti(C_5H_5)_2R\}_2(N_2)]$ (R = certain aryl or alkyl groups) are well characterized [34]. Such compounds might well arise from reduction of $[Ti(C_5H_5)_2Cl_2]$ by a Grignard or alkyllithium reagent under dinitrogen. Although $[\{Ti(C_5H_5)_2N_2\}_2N_2]$ has been established [35], the existence of a related species $[\{Ti(C_5H_5)_2\}_2(N_2)]$ is less certain. Two different routes have been proposed for the reduction of these dinitrogen compounds.

TEUBEN has suggested titanium – cyclopentadienyl ring cleavage [36]:

Intermediate **7** is considered to be a precursor of diazene upon hydrolysis, whereas **8** is a hydrazine derivative. With correct choice of reagents, yields of ammonia can reach 1 mol per atom of titanium.

With RMgCl or RLi as reductant (R = Me, Et, or Pr^i), SHILOV [37] envisages a different reac-

Table 5. Some systems that reduce dinitrogen in aqueous methanol ($p_{N_2} \approx 10$ MPa) [38]

Principal metal ion	Reducing agent	Products	Yield [a]	Temperature, °C
Mo^{III}	$Ti(OH)_3$	N_2H_4, NH_3	1	60
Mo^{III}	$Ti(OH)_3 + Mg(OH)_2$	N_2H_4, NH_3	170	110
	$Ti(OH)_3 + Mg(OH)_2$ without Mo	N_2H_4, NH_3	0.005	180
Mo^{III}	$CR(OH)_2$	N_2H_4, NH_3	0.80	90
	$Cr(OH)_2$ without Mo	N_2H_4, NH_3	0.015	90
V^{II}	$V(OH)_2 + Mg(OH)_2$	N_2H_4, NH_3	0.65	20 [b]
V^{II}	$V(OH)_2 + Mg(OH)_2$	N_2H_4, NH_3	0.35	20 [c]
Nb^{III}	$Nb(OH)_3$	N_2H_4, NH_3	0.09	35
Ta^{III}	$Ta(OH)_3$	N_2H_4	0.02	35

[a] Moles per mole of principal metal ion.
[b] In water, pH > 12.5.
[c] In water, pH < 12.

tion sequence in which the Ti−R bond is ruptured and the $Ti(C_5H_5)_2$ moiety remains intact.

Which of these mechanisms is the more likely under any given conditions is not yet clear.

7. Nitrogen Fixation in Protic Solvents

Metal Hydroxide Systems. It is convenient to classify systems that fix nitrogen in aqueous solution by their principal discoverers. By far the largest group of such systems must be attributed to A. E. SHILOV and his collaborators.

Many hydroxo species can interact with dinitrogen at high pH to yield hydrazine and/or ammonia; some of these function at 101.3 kPa of nitrogen pressure. These systems are all heterogeneous, which makes detailed mechanistic analysis difficult.

In a typical experiment, a gel hydroxide of Cr^{II}, V^{II}, Ti^{III}, Nb^{III}, or Ta^{III} is produced by addition of strong base to a solution of an appropriate salt. In the case of Cr^{II} and Ti^{III}, the presence of Mo^{III} increases the yield, but this is not necessary for the other metal ions. The product is pH-dependent, hydrazine predominating over ammonia as the pH increases. In many cases, such as V^{II}, the presence of an excess of Mg^{2+} is required for maximum activity. Yields and products are listed in Table 5 [38].

Homogeneous systems related to the hydroxide gel systems have also been developed. Thus, V^{II} and a polyphenol (by far the best yields are obtained with catechol) reduce dinitrogen to ammonia only in the narrow pH range 9 – 11. Typically, at a nitrogen pressure of 10.13 MPa in aqueous methanol, the yield of ammonia is 0.75 mol per mole of vanadium [39].

Electrochemical Reduction of Dinitrogen. An electrochemical system has been developed starting with Ti^{III}/Mo^{III} and utilizing a mercury cathode as a source of electrons [40]. In the presence of guanidine this is also homogeneous [41]. Under optimum conditions, the current yield with respect to hydrazine reaches 43 %, but only 4 % with respect to ammonia. Note that the solutions used are often very dilute and that the amount of products are therefore often very small (Table 6) even where they indicate high turn-over numbers [38].

Table 6. Electrochemical reduction of dinitrogen [38]

System*	Products	Yield**
$Mo^{III} + Na(Hg) + Mg^{2+}$	N_2H_4	2.5
Mo^{III} + Hg cathode + $Ti(OH)_3$	N_2H_4, NH_3	0.5
Mo^{III} Hg cathode + $Ti(OH)_3$ + guanidine	N_2H_4	0.15

* In aqueous methanol at 20 °C: $p_{N_2} \approx 10$ MPa.
** Moles per mole of molybdeum.

Catalytic Fixation in Aqueous Systems. The electrochemical system shows that genuine catalytic fixation under aqueous conditions should be possible. This has actually been achieved with the $Ti^{III}/Mg^{II}/Mo^{III}$ system at 110 °C (see Table 5). In the presence of sodium amalgam (or a mercury cathode), molybdenum (+ Mg^{II}) can mediate the conversion of dinitrogen to hydrazine and ammonia. The presence of the phospholipid phosphatidylcholine enhances the yield, as does the presence of tertiary phosphines (see Table 7, which includes data for molybdenum nitrogenase for comparison) [42, 43].

Table 7. Catalytic nitrogen fixation in aqueous systems [41,42]

System	Nitrogen pressure, MPa	Specific rate, moles of N_2 reduced per atom of Mo per second	Yield (N_2H_4 + 1/2 NH_3) Per atom of Mo (turnover number)	Per equivalent reducing agent, %
Mo^{III} + Na(Hg)	7	< 0.0001	0.5	0.004
+ Mg^{2+}	7	0.003	2.5	0.02
+ Mg^{2+} + PC∗	7		25	0.25
+ Mg^{2+} + PC∗	0.1	0.05	3.5	0.03
+ R_3P	0.1	0.4	200 – 1000	5 – 10
+ R_3P	7		10 000	30
Nitrogenase	0.1	0.6		

∗ PC = phosphatidylcholine.

Figure 12. Proposed mechanism for the reduction of dinitrogen by molybdenum – lipid – phosphine systems [37]

Phosphatidylcholine is believed to coat the surface of the amalgam, forming a bridge between the electron donor and the molybdenum catalytic center. It also presumably hinders hydrogen evolution.

SHILOV has discussed the mechanisms of these reactions at some length [38]. Metal ions with three *d*-electrons are believed to be the most favorable for dinitrogen reduction, probably in polynuclear arrangements to facilitate multielectron transfers. A bridging complex of dinitrogen is envisaged as the key intermediate. These ideas are supported by considerable circumstantial physical evidence, but they cannot be regarded as fully proven. The mechanism proposed for these reactions is shown in Figure 12.

8. Other Aqueous Fixation Systems

8.1. Approaches to Models for Nitrogenases

The other considerable body of work on aqueous systems is associated with SCHRAUZER. He showed initially that suitably complexed and buffered molybdenum compounds are capable of mediating the conversion of dinitrogen to ammonia and of ethyne to ethene and ethane, typical reactions of nitrogenase. These studies form part of a series of about 20 papers devoted to the development of a model for nitrogenase function [44].

Molybdocysteine Models. Several molybdenum species have been shown to reduce dinitrogen. One is a derivative of cysteine, formulated as shown below in its reduced form, although this may not be absolutely correct in detail [45].

It is believed to bind dinitrogen side-on and to reduce it to the level of diazene as the molybdenum is oxidized. Diazene is released and then disproportionates or is reduced by more reduced

catalyst. A typical suggested stoichiometry for the system is

$$6e^- + 6H^+ + 3N_2 \longrightarrow$$
$$3N_2H_2 + 2H^+ + 2e^- \rightarrow 2N_2 + H_2 \quad / \quad 2NH_3$$

and is consistent with the stoichiometry of dinitrogen reduction by nitrogenase.

Cyano Complexes. A more efficient system starts from $K_4[MoO_2(CN)_4] \cdot 2\,H_2O$ dissolved in an acetate buffer. With a solution containing 42 µmol of this salt in 4 cm^3 of 0.25 % acetate buffer (pH 4.3, 65 °C, nitrogen pressure 101.3 kPa), the yield of ammonia approached 0.91 µmol. The intermediate formation of hydrazine was also observed [46].

Reduced Peptides as Ligands to Molybdenum. Reduced peptides such as bovine insulin can also give rise to efficient fixing systems, and in this case the rate of reduction is claimed to reach 2.5 mol of dinitrogen per atom of molybdenum per minute, which is about 5 % of the rate exhibited by nitrogenase [47].

8.2. Mechanisms

All of Schrauzer's systems are suggested to function through side-on binding of a dinitrogen to a Mo^{IV} species, followed by conversion of Mo^{IV} to Mo^{VI} and generation of diazene. This is contentious. SCHRAUZER also studied the V^{II}/Mg^{II} [48] and the Mo^{III}/Ti^{III} [49] gel systems of Shilov and concluded that the characteristics of these systems are more compatible with his side-on mechanism than with Shilov's bridging mechanism. The situation is not clear.

9. Fixation of Nitrogen Involving Metal Clusters

Although molybdenum is believed both to be the active site and to be contained in a metal–sulfur cluster in molybdenum nitrogenase, nitrogen fixation by metal clusters has not been definitively proven. Some clusters may be efficient electron-transfer agents to catalysts, but the few claims of fixation by clusters either have been disproved or have yet to be confirmed. One of the most complete studies is of the reduction of dinitrogen by $[Fe_4S_4(SPh)_4]^{2-}$ and $[Mo_2Fe_6S_8(SPh)_9]^{3-}$ under conditions of controlled potential electrolysis in methanol–tetrahydrofuran [50]. The 3− and 5−cluster anions are said to be responsible for binding and reducing dinitrogen, respectively. Yields of up to 3.4 µmol of ammonia were produced by 16 µmol of cluster after 24 h electrolysis at 25 °C. In aqueous solutions, 3.5 µmol of molybdenum cluster can produce 7 µmol of ammonia in 4 d, which may indicate a genuine electrocatalysis.

10. Photochemical Fixation Processes

Photochemical processes can be used to overcome the activation energy barrier to ammonia synthesis. The production of dihydrogen by photochemical splitting of water has been extensively investigated. In particular, iron-doped anatase or iron-doped rutile (TiO_2) under mercury-light irradiation is a good catalyst for the production of dihydrogen and dioxygen. In the presence of dinitrogen, ammonia is also produced, together with some hydrazine [51]. Yields of ammonia and hydrazine vary with time of reaction, temperature, and nitrogen pressure. The overall equations can be written as follows.

$$N_2 + 3\,H_2O \xrightarrow[TiO_2]{h\nu} 2\,NH_3 + 3/2\,O_2$$
$$N_2 + 2\,H_2O \xrightarrow[TiO_2]{h\nu} N_2H_4 + O_2$$

Both reactions are endothermic.

Iron-doped TiO_2 was prepared by impregnating anatase with solutions of iron(III) sulfate and heating the resulting powder to 1000 °C in air for 1–4 h. The product was exposed to mercury arc irradiation for 1–3 h in the presence of the reactants. In a typical experiment, 6.0 ± 2.5 µmol of ammonia and 0.19 ± 0.07 µmol of hydrazine were produced by 3-h irradiation of 0.2 g of catalyst (0.2 wt % Fe_2O_3) at 40 °C under a nitrogen pressure of 101.3 kPa. This fixation process is also exhibited by certain desert sands [52], and it has been suggested that similar processes

may have contributed to the terrestrial stock of fixed nitrogen. The mechanism of this process has not been established. SCHRAUZER believes that diazene is involved as an intermediate but does not discuss the reaction route in great detail. However, it has also been postulated that the N_2/H_2O reaction over rutile proceeds via an oxidative route involving formation of hydrogen peroxide:

$$\begin{array}{lll} & OH^-_{ads} + \text{positive hole} & \xrightarrow{TiO_2} OH^{\bullet}_{ads} \\ & 2OH_{ads} & \longrightarrow H_2O_{2_{ads}} \\ & H_2O_{2_{ads}} & \longrightarrow H_2O_{ads} + O^*_{ads} \\ & N_{2(g)} + O^*_{ads} & \longrightarrow NO^*_{ads} + N_{ads} \\ & N_{ads} + O^*_{ads} & \longrightarrow NO^*_{ads} \\ \text{or} & N_{ads} + O_{2_{ads}} & \longrightarrow NO^*_{ads} + O_{ads} \end{array}$$

where the asterisked species are either neutral or anionic [53]. Although this process may also have significance terrestrially under certain circumstances, the species involved have only been detected spectroscopically.

11. Oxidative Fixation Processes

Oxidative processes for the fixation of nitrogen are no longer commercially viable, the arc process for the conversion of dinitrogen to nitrogen(II) oxide having ceased production in the early 1940s [54]. The synthesis of calcium cyanamide by reaction of calcium carbide with dinitrogen in an electric furnace is part of a commercial route to cyanide but is is not generally competitive for fertilizer production.

At relatively high temperature, metal oxides can oxidize dinitrogen to oxides of nitrogen, but no commercial applications have resulted. An attempt is currently being made to use off-peak electricity to energize a mobile arc system that could be used to supply fixed nitrogen directly to agricultural land. The whole apparatus is planned to moved on a railway track, for example [55]. It is not clear whether this is commercially viable. A very imaginative low-technology application of the arc process based on renewable energy resources (such as sun, wind, and water) has been developed. This is intended to provide nitrate fertilizer to farmers in remote areas and should cost only a few hundred dollars. The prototypes appear to function satisfactorily. Whether this approach will be successful in the field is still not clear [56].

1. Introduction

The noble gases helium (He), neon (Ne), argon (Ar), krypton (Kr), xenon (Xe), and radon (Rn) form group 18 of the periodic table. They are mixtures of numerous isotopes. Table 1 lists the stable natural isotopes and their abundances.

Table 1. Stable isotopes of the noble gases

Element	Atomic number	A_r	Mass number	Abundance, %
Helium	2	4.0026	3	0.000137
			4	99.999863
Neon	10	20.179	20	90.92
			21	0.257
			22	8.82

Only radioactive isotopes of radon, with mass numbers 199 – 226, are known, several of which were formerly referred to by the archaic term emanation. The most important radioactive isotopes of the noble gases, together with their half-lives, are as follows (∗ denotes a metastable state of the isotope):

^{19}Ne	18 s
^{23}Ne	38 s
^{24}Ne	3.38 min
^{37}Ar	34.3 d
^{41}Ar	1.83 h
^{77}Kr	1.2 h
^{81}Kr	2.1×10^5 a
^{85}Kr∗	4.4 h
^{85}Kr	10.76 a
^{87}Kr	76 min
^{125}Xe	18 h
^{131}Xe ∗	12 d
^{133}Xe ∗	2.3 d
^{133}Xe	5.27 d
^{135}Xe	9.1 h
^{199}Rn – ^{226}Rn	0.27 μs – 3.32 d

All of the noble gases exist as gases under standard conditions. Because their structures consist of very stable closed shells of electrons, the noble gases are chemically extremely unreactive. Only krypton, xenon, and radon form chemical compounds, and these only with the most electronegative elements (F, Cl, O). General literature can be found in [1–5].

History. The first investigations of solar protuberances were performed during the solar eclipse of 1868. One of the most prominent emission lines was a bright yellow line at 587.6 nm, which in 1869 was also found in the spectrum of the chromosphere and was originally attributed to hydrogen. LOCKYEAR believed that the line was due to a new element, which was given the name helium by FRANKLAND and LOCKWOOD because of its occurrence in the sun (*helios*, the sun) [6]. In 1885 RAMSAY and CROOKES identified terrestrial helium, formed by dissolution of the uranium mineral cleveite in acids. In the same year KAYSER demonstrated by means of spectroscopy that helium also occurs in the earth's atmosphere. The other noble gases were discovered between 1884 and 1889 by RAYLEIGH, RAMSAY, and TRAVERS, partly using the air liquefaction process developed by VON LINDE. The initiative for this work was provided by precise measurements of the density of atmospheric nitrogen obtained by absorbing the oxygen with copper, and of nitrogen prepared chemically from nitrogen compounds such as nitrous oxide, nitric oxide, ammonia, or urea. Having removed the oxygen from air, RAYLEIGH and RAMSAY treated the nitrogen with red-hot magnesium turnings. The spectrum of the residual gas exhibited a series of previously unknown red and green lines. The ratio of the

specific heats ($C_p/C_v = 1.66$) indicated the presence of a monoatomic gas. They attributed these lines to a new element, which they later named argon on account of its low reactivity (the idle). The discovery of argon was followed by krypton (the hidden), neon (the new), and xenon (the strange). The unstable isotopes of the last noble gas radon were discovered as products of various radioactive decay series in 1900 – 1904 by RUTHERFORD et al. Summaries are given in [7, 8].

KAMERLINGH ONNES achieved the liquefaction of helium in 1908, thereby establishing a new temperature range which lay a factor of ten closer to absolute zero than was attainable with liquid hydrogen. Solid helium was first obtained in 1926 by KEESOM by using high pressure.

Although the high helium contents of U.S. natural gas had been known since 1805, up to 1917 helium was prepared only in laboratory quantities from uranium and thorium minerals. The production of helium from natural gas in the United States by means of cryogenic technology was initiated by SEIBEL.

Shortly after its discovery, the bright red light emitted by neon in the Geissler tube suggested its use in illumination. Although the first neon sign, containing a neon mixture, was manufactured by Griesheim – Elektron in 1913, it was only much later that pure neon was produced. In 1960, 10 L of liquid neon was transported for the first time. Also in 1913, LANGMUIR discovered that the light yield and life of incandescent bulbs could be increased when the bulb was filled with an argon-rich argon – nitrogen mixture instead of being evacuated. Thus the use of argon for illumination commenced. Large-scale production of argon first became feasible with the patenting of processes by L'Air Liquide (1920) and the Gesellschaft für Linde's Eismaschinen (1914). Up to 1930 krypton and xenon were prepared in small amounts by rectification of liquid air. Only after these gases became important in lighting applications were they prepared on a large scale.

Noble gases are now of major importance in modern technology. Production of pure argon increased greatly in the United States after 1943, in the Federal Republic of Germany from 1950, and subsequently worldwide due to its increasing use as a protective gas for the production and processing of metals. Compounds of the noble gases were predicted, among others, by PAULING [9]. In 1962 BARTLETT [10] and HOPPE [11] independently prepared xenon compounds. These discoveries led to a rapid development of the chemistry of xenon.

2. Properties

2.1. Physical Properties

2.1.1. Single-Component Systems

The noble gases are colorless, tasteless, odorless substances that exist in the gas state under standard conditions. The electron distribution in the atoms is spherically symmetrical. Therefore, the noble gases, particularly ^{3}He and ^{4}He, are often used as model substances for testing physicochemical theories. The interactions between noble gas atoms consist of weak van der Waals and London forces whose magnitude is directly proportional to the polarizability and inversely proportional to the ionization potential of the atoms. These relationships determine the gradation of properties among the noble gases. For example, the boiling points are proportional to the square root of the polarizibility, and the critical temperatures are proportional to the reciprocal ionization potentials.

Some physical properties of the noble gases are listed in Table 2. Since the isotopes ^{3}He and ^{4}He differ greatly in some of their properties, they are listed separately. Owing to the rarity of radon, its properties have not been studied extensively, and the values are less accurate than for the other noble gases. More recent listings of the thermophysical properties are given in [12] for helium, and in [13] for neon, argon, krypton, and xenon.

Solid and Liquid ^{3}He and ^{4}He [14–17]. The vapor pressure of ^{3}He and ^{4}He is listed in Table 3. Liquid and solid ^{3}He and ^{4}He exhibit properties that are not observed for any other substances. They are the only elements that do not possess a triple point, they remain liquid down to absolute zero upon cooling under their own vapor pressure, and freeze only under high pressure. For example, the minimum pressure for the solidification of ^{3}He at 1 K is 4.011 MPa and at 3 K, 12.9 MPa. The corresponding values

∗ The log $p-(1/T)$ curves from various sources exhibit differing positions and gradients. Here, the formula $\log(p/\mathrm{Torr}) = 7.4955 - 884.41/(250.0+t)$ [33] was used for liquid radon, and for solid radon, Table 33 from Ref. [33].

∗∗ Ref. [34] gives the following values: 10^{-3} bar at 73.84 K and 10^{-2} bar at 84.39 K.

Figure 1. A) Phase diagram of ^{4}He; B) Phase diagram of ^{3}He in the existence range of the superfluid modification [27]

for ^{4}He are 2.5347 MPa (1 K) and 7.996 MPa (3 K). The melting point – pressure curves of ^{3}He [18–20] and ^{4}He [21–23] have been measured up to very high pressures; extrapolated values are given in [24]. The curves exhibit a minimum at low temperature. At the temperature of the minimum, the heat of melting is zero. Below this temperature, heat is liberated upon melting; i.e., heat must be supplied for helium to freeze. Both helium isotopes form three solid allotropes (see Figs. 1 A [17,24–26] and B [27]).

Helium I and Helium II. If boiling ^{4}He (^{4}He-I) is cooled by lowering the pressure, it does not solidify. Instead, it undergoes a second-order transformation at 2.177 K and 5.04 kPa to give a new liquid phase, ^{4}He-II. The existence ranges of the two phases are separated by the λ-line. Whereas ^{4}He-I behaves as a normal fluid, ^{4}He-II exhibits unusual properties, so that anomalies are observed upon the phase transition ^{4}He-I $\rightarrow$ ^{4}He-II.

Thus, upon pumping down boiling ^{4}He-I, the liquid suddenly becomes calm when the λ-point is reached. The smooth surface of the liquid forms an extremely sharp meniscus at the wall of the vessel, although in fact the ^{4}He-I continues to evaporate. The reason for this behavior is that at the λ-point the viscosity undergoes a millionfold decrease while the thermal conductivity increases by a factor of a million. Near absolute zero, the viscosity becomes zero, and ^{4}He-II is a frictionless superfluid. ^{4}He-II flows over obstacles that lie above the miniscus to reach the lowest attainable level. If a vessel is filled by dipping into a bath of ^{4}He-II and then raised above the surface of the bath, the ^{4}He-II flows as a film up the inner wall of the vessel, over the edge, down the outer wall, and drips from the bottom of the vessel back into the bath.

In saturated ^{4}He-II vapor, solid surfaces are covered with a film of ^{4}He-II about 100 atomic diameters thick. The film moves across the surface completely without friction up to a critical

velocity of 30 cm/s. The frictionless flow of ^{4}He-II is also observed in capillaries up to a diameter of 0.001 cm. The superfluidity of ^{4}He-II gives rise to unusual thermomechanical effects. When two vessels containing ^{4}He-II are linked by a small opening, a capillary, or a surface coated by ^{4}He-II, ^{4}He flows from the colder vessel to the warmer vessel. The flow of cold ^{4}He-II through a capillary into a warmer vessel is best demonstrated by the so-called fountain effect. A periodic addition of heat to ^{4}He-II is propagated as a wave (second sound), whereas in other substances a thermal wave is immediately damped and the energy dispersed [28]. The thermal conductivity of ^{4}He-II is ca. 3×10^6 greater than that of ^{4}He-I and ca. 200 times greater than that of copper at 20 °C.

The anomalous behavior results from quantum effects, although it has not been explained completely; ^{4}He-II is often referred to as a quantum fluid [29]. Many of the properties of ^{4}He-II can be explained qualitatively by the two-liquid model [14,30], which regards ^{4}He-II as being a mixture of two interpenetrating liquids, one a normal fluid like ^{4}He-I and the other a perfect superfluid. The concentration of the superfluid is taken as 0 % at the λ temperature and 100 % at 0 K. Superfluidity has also been observed for ^{3}He, but only below 2.6×10^{-3} K. Two superfluid phases, designated A and B, were detected. The intersection of the λ-line with the melting point – pressure curve is at 2.6 ± 0.1 mK and 3.44 MPa [31] (cf. Fig. 1 B); a summary is given in [27,32].

Solid and Liquid Neon, Argon, Krypton, Xenon, and Radon. In contrast to the trimorphic helium isotopes, all other noble gases crystallize in face-centered cubic structures. Vapor pressures are given in Table 3; the melting behavior is described in [35–38]. Solid or liquid radon phosphoresces due to its radioactivity.

Properties of the Gases. After hydrogen, helium is the lightest gas. At 15.5 °C and 101.3 kPa, 1 3 of ^{3}He weighs 0.1211 kg, 13 ^{4}He weighs 0.1607 kg, 13 hydrogen weighs 0.0810 kg, and 13 air weighs 1.16307 kg. Hence the buoyancy of helium in air is 1.00237 kg/m^3 and that of hydrogen 1.08207 kg/m^3. The slightly lower buoyancy and higher cost of helium as a balloon gas are balanced out by its nonflammability and by its rate of diffusion through balloon envelopes– 65 % lower than that of hydrogen.

Helium-3. The $H-T$ $(0<p<6.6\,\text{bar})$ and $H-p$ diagrams can be found in [39]; further thermodynamic properties are given in [40].

Helium-4. The temperature dependence of the properties of ^{4}He is shown in Table 4. Further thermophysical properties for temperatures of 4 – 3000 °R and 1500 psia are given in [23]; for 2 – 1500 K and up to 10^3 atm in [22,41]. Numerical coefficients of the functions $T(p,H)$, $\varrho(p,H)$, $S(p,H)$, $H(p,S)$, and $H(p)$ at the phase boundaries, based on the data in [41], can be found in [43]. Older values for 3 – 300 K and 0.5 – 100 atm, and for 5 – 540 °R and 10 – 1500 psia are given in [44,45]. Thermodynamic properties up to 50 000 K can be found in [46].

Neon. The temperature dependence of some physical properties of neon is shown in Table 5. Values of the coefficient of compressibility in the range 80 – 130 K and 75 – 2072 bar are given in [48]. Calculated values of the specific entropy and enthalpy are listed in [49].

Argon. The temperature dependence of some properties of argon is shown in Table 6. Values in the range 90 – 600 K and 1 – 5000 atm can be found in [51], while calculated values for 300 – 35 000 K and $\log p$ from -4.9 to $+4.2$ are given in [52].

Krypton. Values of p, V, T from 130 to 240 K are given in [53]; values for 0 – 150 °C and 0 – 1000 bar can be found in [54], together with calculated thermodynamic properties as a function of the Amagat density (the relative density divided by the relative density under standard conditions $\varrho_{T,P}/\varrho_{273.15,\,101.3\,\text{kPa}}$). Equations of state for 120 – 423 K and 0 – 1000 bar are given in [55], and for 120 – 1300 K and 0 – 1000 bar in [56].

Xenon. The p, V, T isotherms for the range 0 – 150 °C and 0 – 2800 atm are given in [57], and calculated values as a function of the Amagat density in [58] (see also [33]).

Like polyatomic gases, the noble gases do not follow the ideal gas laws (Fig. 2). For helium and neon, repulsive forces between the atoms dominate down to relatively low temperatures. Therefore, they are the only gases, apart from hydrogen and deuterium, that undergo a temperature increase upon expansion at normal temperatures.

Figure 2. Compressibility coefficients of the noble gases compared to those of several polyatomic gases at 0 °C

The specific heat of the noble gases is independent of temperature and pressure over a wide range. The ratio C_p/C_v has the limiting value

$$\frac{\frac{3}{2}R + R}{\frac{3}{2}R} = 1.667.$$

Because they are monoatomic, the noble gases do not exhibit sound dispersion. The coefficients of the thermal conductivity λ, viscosity η, and diffusion D are given by

$$\lambda M_r/\eta C_v = f_1 \text{ and } D\varrho/\eta = f_2$$

where M is the relative molecular mass, C_v the molar heat capacity at constant volume, and ϱ the density. The function f_1 is a constant over a wide temperature range and has the value 2.5 corresponding to that expected for a monoatomic gas consisting of rigid balls. For ^{4}He, f_1 decreases below 100 K: at 81.4 K it is 2.44 and at 20.9 K, 1.99. The value of f_2 is ca. 1.3; it decreases slowly with increasing temperature. Table 7 lists values for λ and η. The values of λ and η increase with increasing pressure [62–65]. In the range 80 – 300 K, the viscosity of ^{3}He is ca. 15 % lower than that of ^{4}He [66].

2.1.2. Two- and Multicomponent Systems

Mixtures of Liquid ^{3}He and ^{4}He. The large differences in the physical properties of the helium isotopes is also demonstrated by their limited miscibility below 0.87 K (Fig. 3). Theoretically, phase separation is expected near absolute zero. The finite solubility of ^{3}He in ^{4}He

Table 8. Solubility of helium in vacuum pump oils [84]

60	0.94	2.12	1.29
80	1.02	2.38	1.46

∗ mmol He per kg oil at $p_H^e = 100$ kPa.

of 6.37 mol % was, however, unexpected. This anomalous behavior of $^3He-^4He$ mixtures is exploited in $^3He-^4He$ refrigerators for temperatures in the range $<<$ 100 mK to 1 mK [68–72].

Figure 3. $^3He-^4He$ phase diagram [67, 70]

The melting behavior of binary mixtures containing argon, krypton, and xenon is described in [73] ($Ar+F_2$); [74, 75] ($Ar+CH_4$); [76] ($Ar+Kr$); [77] ($Ar+N_2$); [78] ($Ar+Xe$); and [79] ($Kr+CH_4$).

Solubility. The solubility of noble gases in liquids depends on the size (formation of interstices in the solvent) and deformability of the noble gas atoms (interaction between the dissolved atoms and the solvent). The very small helium atoms, in particular, can readily find interstices for their absorption, so that helium has a finite solubility, despite the extremely low deformability of its atoms. The solubility of helium is in most cases lower than that of all other gases. The solubility coefficient mostly decreases at high pressures. With increasing atomic volume, the interactive forces are dominant, and the solubility increases greatly from helium to radon. The solubility in nonpolar organic solvents is usually higher than in water. Dissolved electrolytes generally lower the solubility; exceptions are LiCl and LiI for helium, and $HClO_4$ for helium and argon. Solubility values for helium and neon are given in [80], for argon in [81], and for krypton, xenon, and radon in [82]. The solubilities of helium in some low-volatility oils are listed in Table 8; further values can be found in [83, 84].

Phase Equilibria. Because of theoretical interest and their importance for the separation of industrial gas mixtures, the solid – gas and liquid – gas equilibria of numerous binary, ternary, and multicomponent systems containing noble gases have been measured over wide ranges of temperature and pressure [85, 86]. Helium-3 and helium-4 exist in the supercritical state in the existence range of all other liquified gases. Therefore, as is the case with other supercritical gases the lens-shaped area enclosed by the boiling point curve and the dew point curve in the P, x, y or T, x, y diagrams does not reach the limiting value of 100 mol % He. The solubility of helium in liquid nitrogen and liquid methane [76] is given in Table 9 (see next page).

Table 9. Solubility of helium in liquid nitrogen and liquid methane at various temperatures [87]

Total gas pressure,	Solubility, mol %					
	in N_2			in CH_4		
MPa	64.9 K	95 K	120 K	95 K	124.9 K	184.8 K

14.18		5.785	14.26	0.410	1.58	10.17
18.24				0.503	1.92	12.70

Gas – Gas Equilibria. Phase separation in the gas state has been observed at high pressure in many systems containing noble gases as components (first- and second-order gas – gas equilibria). Therefore, the critical curve and the miscibility gap extend well beyond the critical temperatures and pressures of the components [88]. Further work can be found in the literature: $He + H_2$, 0 – 10 kbar [89,90]; $He + N_2$, 0 – 4.3 kbar [91]; He + Ne [92]; H_2 + Ar [93]; Ne + Ar, 0 – 1 kbar [94]; Ne + Kr, 0 – 1.9 kbar [95].

Permeation. In contrast to hydrogen, noble gases are insoluble in solid and molten metals. Therefore, metals are impermeable up to high temperatures (red heat), even for the small helium atom. The permeation coefficient P for unalloyed and high-alloy creep-resistant steels free of lattice defects at 1160 – 1290 °C and a pressure difference of ca. 11 bar is less than 10^{-13} mmol $s^{-1} \cdot cm^{-1} \cdot bar^{-1}$ [96]. The extremely low permeation of helium is, in addition to the fact that only its very small content of ^3He can be activated by neutrons, of major importance for the cooling of nuclear reactors. Single crystals such as beryl (P_{He} 10^{-14} at 20 °C), fluorspar ($< 3 \times 10^{-15}$), mica ($< 10^{-16}$), calcite and quartz ($< 5 \times 10^{-16}$), selenite ($< 10^{-16}$), and rock salt ($< 10^{-13}$) are also practically impermeable to helium. The differing permeabilities of minerals are important in the formation of helium deposits and for determining the age of rocks. The permeability of inorganic glasses depends on their composition and pretreatment (Fig. 4). The permeability for helium increases with increasing proportion of glass-formers (SiO_2, B_2O_3, P_2O_5). Even at low temperatures, the permeation of helium through glass is sufficiently high that Dewar vessels containing liquid helium must be periodically or continuously re-evacuated. The permeation through glass decreases with increasing atomic radius of the noble gases.

Helium has a high permeation rate in organic materials. Permeability coefficients for various organic and inorganic polymer membranes are listed in Table 10. The coefficients are mostly considerably higher than those of methane and nitrogen, so that high selectivities can be attained. The high permeability and selectivity of membranes for helium are exploited in its separation from natural gas (see Section 4.2).

Table 10. Permeability coefficients of helium, nitrogen, and methane in inorganic and organic membrane materials

Membrane material	Temperature, °C	Permeability coefficient $P \cdot 10^{10}$, $\frac{cm^3 (STP \cdot cm)}{cm^2 \cdot s \cdot cm\,Hg}$			Selectivity α

Aromatic polyimide (Pyrrolone) [101]	35	89	1.2	0.54	74	165

In organic nonporous polymer membranes normally the solubility increment of the permeability prevails. Therefore, in contrast to inorganic membranes, the permeability coefficient of the noble gases increases together with their solubility, which is higher at higher atomic masses. Thus xenon and krypton have higher permeability coefficients than the lighter noble gases argon and helium and the other constituents of air; e.g., with polydialkylsiloxane, $P_i \cdot 10^{10}$ [cm^3 (STP) $\cdot$ cm/($cm^2 \cdot s \cdot cm$ Hg)] at 20 °C is as follows: He, 230; N_2, 184; Ar, 401; Kr, 750; Xe, 1660 [99].

Kryptonates are solids whose surfaces contain intercalated krypton atoms. The intercalation can occur by bombardment of the solid by krypton ions, through diffusion at high temperature and pressure, or by tribosorption (e.g., working of metals in a krypton atmosphere). Kryptonates are stable at high temperatures, regardless of how they were prepared. The krypton occupies only the outer lattice positions up to a depth of 10^3 nm. The use of kryptonates in nuclear technology for the retention of radioactive fission gases has been suggested [102, 103].

Adsorption. Examples of the general adsorption behavior of the noble gases are shown in Figures 5 and 6 (see next page). Older results for activated carbon are given in [106, 107]. The adsorption of krypton and xenon on activated carbon, silica gel, and zeolites has been studied extensively because of its possible applications in reducing the pressure of heavy noble gases formed in nuclear fuel elements and for retaining radioactive fission gases [110–116].

The adsorption enthalpy decreases with increasing loading of the adsorbent (Fig. 7); it is usually 1.5 – 3 times larger than the heat of vaporization [117]. The lines of constant loading in the diagrams log p_i or log f_1 versus $1/T$ are linear over wide ranges. Therefore, like the gas – liquid phase equilibrium, the adsorption equilibrium follows the Clausius – Clapeyron law. The specific heat of the adsorbed gases is about one-third that of the solid noble gases.

Krypton and xenon cannot penetrate narrow-pored Na – K A zeolites at room temperature and are therefore not adsorbed. However, at high temperatures the gas atoms can be forced into the zeolites. When the resulting krypton-loaded molecular sieve (Na/K, 60/40) is cooled, the pores become smaller again, and the krypton remains trapped with almost zero leakage [118]. The gas can be liberated by heating.

The noble gases are used for testing theories of adsorption and, in particular the lighter members of the group, for determining the surface area of adsorbents, catalysts, and powders (BET method).

Figure 5. Adsorption isotherms for krypton and xenon on pyrex glass [104]

Figure 6. Adsorption isotherms of helium on activated carbon (a) and zeolites (b) at 76 K [105]
V_T is the excess of gas present in the pores of the adsorbent relative to the amount that would be present at normal density and equilibrium pressure. V_E is the total amount of gas held in the pores by adsorptive forces

2.2. Chemical Properties

The electronic configurations of the noble gases, which are characterized by filled shells of electrons, are as follows:

He		$1s^2$			
Ne	[He]	$2s^2$	$2p^6$		
Ar	[Ne]	$3s^2$	$3p^6$		
Kr	[Ar]	$3d^{10}$	$4s^2$	$4p^6$	
Xe	[Kr]	$4d^{10}$	$5s^2$	$5p^6$	
Rn	[Xe]	$4f^{14}$	$5d^{10}$	$6s^2$	$6p^6$

The stability of the noble gases with respect to loss or acceptance of electrons is due to their high ionization potentials and the highly negative values of their electron affinities. These effects are essentially responsible for the chemical inertness of these elements.

It was long believed that the noble gases were incapable of forming chemical compounds.

Nevertheless, in 1962 three groups succeeded independently in preparing noble gas compounds. In June 1962 BARTLETT prepared the orange-yellow, moisture-sensitive compound "xenon hexafluoroplatinate" by reaction of Xe with PtF_6. In July 1962 HOPPE obtained the first binary compound of xenon, XeF_2, and this was followed one month later by the synthesis of XeF_4 by CLAASEN, SELIG, and MALM. These discoveries prompted a rapid growth in noble gas chemistry. A summary of the discovery of the noble-gas compounds and a discussion of priority claims is given in [119].

A surprising result was that the valence compounds of krypton and xenon do not involve a new type of chemical bonding. The atoms are bound in the same manner as in the long-known interhalogen compounds, such as IF_7, and in TeF_6. For the formation of noble gas compounds, an electron must be promoted from the p shell to the d shell, after which formation of bonding electron pairs with another atom can occur with hybridization of the type spd^n ($n = 1, 2, 3, 4$). A detailed description of the bonding is given in [120].

Noble gas compounds can be divided into three general types: (1) short-lived molecules containing noble gas atoms, (2) valence compounds, and (3) inclusion compounds (clathrates and intercalation compounds); comprehensive reviews are given in [120–123]. Valence compounds are only formed with the most electronegative elements (till now, F, Cl, Br, N, and C), whereby thermodynamically stable compounds with fluorine are formed only by xenon and radon. The thermodynamic stability of noble gas compounds, for example, the halides, follows the following general rules:

1) The stability of the compounds EX_2 increases with increasing atomic number of the noble gas and with decreasing atomic number of the halogen:

$$ArF_2 < KrF_2 < XeF_2 < RnF_2$$

$$XeF_2 > XeCl_2 > XeBr_2$$

2) The stability of the compounds decreases as the oxidation state of the noble gas increases.

2.2.1. Chemistry of Helium, Neon, and Argon

Extensive theoretical, radiochemical, and mass spectroscopic studies on short-lived ions and molecules have been carried out [124, 125]. Short-lived He_2^{2+} and He^{2-} ions have been theoretically predicted and experimentally detected [126]. The existence of a stable molecule He – Be – O, with a linear geometry, has been predicted on the basis of ab initio calculations [127], as has the formation of covalent bonds between neon or argon and carbon dications (C^{2+}, CC^{2+}) or BeO [128].

Up to now, attempts to react helium, neon, and argon with other elements have failed. Thus, attempts to prepare ArF_2 (estimated decomposition energy 105 kJ/mol) or a compound of the presumably more stable cation ArF^+ were unsuccessful.

2.2.2. Chemistry of Krypton

The chemistry of krypton is limited to the detection of the ions KrF^+ and $Kr_2F_3^+$ and the KrF_2 radical and the synthesis of KrF_2 and its complexes $KrF_2 \cdot 2\,SbF_5$ and $KrF_2 \cdot x\,AsF_5$. A report of the detection of KrF_4 proved to be erroneous. The existence of a compound with a Kr – N bond is claimed in [129].

Krypton (II) fluoride, KrF_2, is only stable below 0 °C. Therefore, it cannot be prepared thermally from the elements, and its synthesis requires strong activation at low temperature. It can be synthesized by:

1) Irradiation of a mixture of Kr and F_2 at − 150 °C with a 1.5 MHz electron beam [130], or at − 140 °C with 10 MeV protons or 40 MeV α-particles [131]
2) Electrical discharge through a 1: 1.1 mixture of Kr and F_2 in a prefluorinated recycling reactor at − 196 °C and 2.5 kPa [132]

Krypton (II) fluoride is now prepared straightforwardly by a photochemical reaction [133]; it is purified by sublimation.

Properties. Krypton (II) fluoride forms colorless, tetragonal crystals that can be stored without decomposition in dry pyrex or PTFE

vessels at $-40\,^{\circ}C$. The vapor pressure at $-40\,^{\circ}C$ is 0.2 – 0.25 kPa; the compound is readily sublimable below $0\,^{\circ}C$ at 4 kPa. The standard enthalpy of formation for the gas is + 60 kJ/mol, and for the solid it is + 15.5 kJ/mol; thus, KrF_2 is metastable. The KrF_2 molecule is linear with a Kr – F bond length of 189.9 pm in the gas phase.

Reactions. Krypton (II) fluoride is hydrolyzed by water and dilute acids and alkalies:

$$KrF_2 + H_2O \rightarrow Kr + 1/2\,{}_2O + 2\,HF$$

Treatment of KrF_2 with SbF_5 gives the adduct $KrF_2 \cdot 2\,SbF_5$, which is composed of $[KrF_2]^+[Sb_2F_{11}]^-$ ion pairs. The compound is colorless and dissolves in excess SbF_5 to form a clear, yellow solution. The $[KrF]^+$ ion can be stabilized by other anions such as AsF_6^-, TaF_6^-, $Ta_2F_{11}^-$, and $Nb_2F_{11}^-$. Hydrolysis of the adducts $KrF_2 \cdot MF_5$ in alkaline or weakly acidic solutions gives krypton, oxygen, and fluorine monoxide. The adducts react explosively with organic compounds. The first compound of two noble-gas fluorides, the adduct $KrF_2 \cdot XeF_6$, which is more stable than XeF_2, was synthesized in 1975 [134]. Krypton – oxygen compounds have not yet been prepared. The most promising attempt– the reaction of KrF_2 with the $OTeF_5$ ligand– was unsuccessful [135]. At $-100\,^{\circ}C$ the reaction gave only elemental krypton. Graphite – KrF_2 intercalation compounds of varying compositions have been obtained by prolonged contact of KrF_2 with graphite [136]. A compound with a krypton – nitrogen bond, $[HC{=}NKrF]^+$ AsF_6^-, has been obtained by reacting KrF_2 with $[HC{=}NH]^+AsF_6^-$ in HF at $-60\,^{\circ}C$; the compound decomposes explosively above $-50\,^{\circ}C$ [137]. Krypton (II) fluoride is one of the most powerful fluorinating agents known. Fluorination reactions with KrF_2 are ca. 50 kJ/mol more exothermic than those with elemental fluorine. It can be used to prepare fluorides of elements in their highest oxidation states, converting Au to Au (V), Xe to XeF_6, and iodine to IF_6.

2.2.3. Chemistry of Xenon

Compounds of xenon are known in the oxidation states II – VIII, some of which are remarkably stable. Xenon (II) fluoride is even commercially available. The most important xenon compounds and some of their properties are listed in Table 11. The cation Xe^+ has been observed in the solid state, whereas Xe^{2+} is observed only in solution in SbF_5 [138].

Xenon Halides. The ions Xe_2F^+, XeF^+, $Xe_2F_3^+$, $Xe_2F_5^+$, XeF_3^+, and $Xe_2F_7^+$ have been detected during mass-spectroscopic studies of xenon fluorides. The compounds $XeCl_2$, $XeCl_4$, and $XeBr_2$ were detected as highly unstable products of the β-decay of $^{129}ICl_2$ and $^{129}ICl_4$. Also, $XeCl_2$ has been detected as a component of the low-temperature condensate obtained after electrical discharge through a mixture of xenon and chlorine.

Table 11. Important xenon compounds

Oxidation state	Compound	Form	*mp*, °C	Structure	Comments
II	XeF_2	colorless crystals	129	linear	hydrolyzes to $Xe + O_2$; very soluble in liquid HF
IV	XeF_4	colorless crystals	117	square planar	stable, $\Delta H_B^{298\circ} = -284\,kJ\,mol^{-1}$
VI	XeF_6	colorless crystals	49.6	complex	stable, $\Delta H_B^{298\circ} = -402\,kJ\,mol^{-1}$
VI	$CsXeF_7$	colorless solid			decomp. $> 50\,^{\circ}C$
VI	Cs_2XeF_8	yellow solid		archimed. antiprism [a]	stable up to $400\,^{\circ}C$
VI	$XeOF_4$	colorless ligand	−46	octahedral [b]	stable
VI	XeO_2F_2	colorless crystals	31	tbp	metastable
VI	XeO_3	colorless crystals		tetrahedral [b]	explosive: $\Delta H_B^{298\circ} = +402\,kJ\,mol^{-1}$; hygroscopic, stable in solution
VI	$n\,K^+[XeO_3F^-]_n$	colorless crystals		qpy F-bridges	very stable
VIII	XeO_4	colorless gas		tetrahedral	explosive
VIII	XeO_6^{4-}	colorless salt		octahedral	the anions $HXeO_6^{3-}$, $H_2XeO_6^{2-}$, $H_3XeO_6^-$ also exist

[a] In the salt $(NO^+)_2\,[XeF_8]^{2-}$, prepared from NOF and XeF_6.
[b] Molecule has an electron lone pair.

Xenon (II) fluoride, XeF_2, is formed in high yield in an exothermic reaction when a mixture of xenon and fluorine (Xe: F_2, 2: 1) is passed through a nickel tube at 400 °C and 2 bar. The XeF_2 is condensed at − 50 °C.

$$Xe + F_2 \rightarrow XeF_2 \quad \Delta H_0 = 164\ \text{kJ/mol}$$

For thermodynamic data and spectroscopic and crystallographic studies, see [120]. The molecule is linear with a bond length of 197.7 pm in the gas phase and 200 pm in the crystal. Xenon (II) fluoride is soluble in water at 0 °C up to 15 M concentration. It undergoes hydrolysis slowly in dilute acid, and rapidly in bases according to:

$$XeF_2 + 2\,OH^- \rightarrow Xe + 1/2\,O_2 + 2\,F^- + H_2O$$

Characteristic for XeF_2 is its strong oxidizing power. The oxidation potential for the reaction

$$XeF_2\ (aq) + 2\,H^+ + 2\,e^- \rightarrow Xe + 2\,HF\ (aq)$$

has been estimated to be 2.64 V. Xenon (II) fluoride acts as a fluoride ion donor towards Lewis acid metal fluorides MF_n (M = As, Sb, B, Al, or Ga), forming the complexes $[XeF]^+[MF_{n-1}]^-$. Xenon (II) fluoride forms a number of covalent derivatives, mainly of the type F – Xe – OL and Xe $(OL)_2$, where L is, for example, TeF_5, SO_2F, or $COCF_3$. Except for the stable pentafluorotellurates, most of these compounds decompose readily and must even be regarded as explosive [123].

Xenon (IV) fluoride, XeF_4, can be prepared by heating xenon with excess fluorine (molar ratio Xe: F_2, 1: 6) for several hours at 400 °C in a nickel vessel

$$Xe + 2\,F_2 \rightarrow XeF_4 \quad \Delta H_0 = -278\ \text{kJ/mol}$$

or through the reaction of XeF_2 with fluorine. Pure XeF_4 can be obtained in quantitative yield by irradiation of XeF_6 [139]. Thermodynamic, spectroscopic, and crystallographic data for XeF_4 can be found in [120]. The compound is stable in the solid state and can be stored in thoroughly dried nickel or glass vessels. The solubility in hydrogen fluoride is 0.18 mol XeF_4/kg HF; the solution is electrically nonconducting. In neutral or acidic solution, XeF_4 undergoes hydrolysis according to:

$$3\,XeF_4 + 6\,H_2O \rightarrow XeO_3 + 2\,Xe + 3/2\,O_2 + 12\,HF$$

In alkaline solutions the yield of XeO_3 is lower due to decomposition. Xenon (IV) fluoride is a stronger oxidizing and fluorinating agent than xenon (II) fluoride. It selectively fluorinates the ring in substituted aromatics such as toluene and reacts rapidly with hydrogen to give xenon and hydrogen fluoride.

Xenon (VI) fluoride, XeF_6, can be synthesized by heating a mixture of xenon and fluorine (molar ratio 1: 20) in a nickel or monel vessel to 700 °C at 200 bar. Thermodynamic data for XeF_6 are given in [120]. Solid XeF_6 is trimorphic:

$$\text{phase III (cubic)} \xleftrightarrow{-19.35\,^\circ C} \text{phase II (cubic)} \xleftrightarrow{18.65\,^\circ C} \text{phase I (triclinic)} \xleftrightarrow{49.47\,^\circ C} \text{liquid}$$

The compound is colorless below 43 °C and yellow above this temperature; the liquid is yellow and the vapor yellow-green. When XeF_6 is sublimed slightly below room temperature, the cubic phase IV is formed. Xenon (VI) fluoride reacts rapidly with quartz

$$2\,XeF_6 + SiO_2 \rightarrow 2\,XeOF_4 + SiF_4$$

and dissolves in anhydrous HF with solvolysis:

$$XeF_6 + HF \rightarrow XeF_5^+ + HF_2^-$$

The yellow solution in HF becomes colorless on cooling, is electrically conducting, and attacks all materials. Xenon (VI) fluoride also acts as a fluoride ion acceptor, as demonstrated by its reactions with alkali-metal fluorides to give hepta- or octafluoroxenate(VI) salts:

$$XeF_6 + RbF \rightarrow RbXeF_7$$

The rubidium and cesium salts are well characterized; they decompose at 20 °C and 50 °C, respectively, according to the equation:

$$2\,MXeF_7 \rightarrow XeF_6 + M_2XeF_8\ (M = Rb\ \text{or}\ Cs)$$

The rubidium and cesium octafluoroxenates are pale yellow solids and are thermally the most stable xenon compounds known, being stable up to almost 400 °C. They react vigorously with water and hydrolyze in air to give xenon-containing products with oxidizing action. Although the compound XeF_8 has been reported itappears not to exist [140].

Xenon Oxides and Oxyhalides. The following xenon oxides and oxyhalides are known:

Oxidation state	IV	VI	VIII
Oxide		XeO_3	XeO_4
Oxyhalides	$XeOF_2$	XeO_2F_2	XeO_3F_2
	$XeOF_4$	XeO_2F_4	

All xenon – oxygen compounds are synthesized from the xenon fluorides.

Xenon(VI) oxide, XeO_3, can be obtained by careful hydrolysis of XeF_6:

$$XeF_6 + 3\,H_2O \rightarrow XeO_3 + 6\,HF$$

or through disproportionation of XeF_4 or $XeOF_4$

$$3\,XeF_4 + 6\,H_2O \rightarrow Xe + 2\,XeO_3 + 12\,HF$$

Colorless crystals of XeO_3 are obtained by evaporating the solution. With a standard heat of formation of 402 kJ/mol, the compound is highly unstable; it is an explosive with an explosive power comparable to that of TNT. The crystals contain isolated XeO_3 molecules with a pyramidal structure, a Xe – O bond length of 176 pm, and a O – Xe – O bond angle of 103°. Xenon (VI) oxide is strongly hygroscopic. Solutions in pure water are stable; xenon concentrations up to 11 mol/L have been attained. Aqueous solutions of XeO_3 are colorless, weakly acidic, and possess a very low conductivity. They contain unchanged XeO_3 and small amounts of H_2XeO_4. The addition of alkali leads to formation of xenate (VI), $HXeO_4^-$, which slowly hydrolyzes to give xenon(VIII) and xenon:

$$XeO_3 + OH^- \rightarrow HXeO_4^-$$

$$2\,HXeO_4^- + 2\,OH^- \rightarrow XeO_6^{4-} + Xe + O_2 + 2\,H_2O$$

Aqueous solutions of XeO_3 are strongly oxidizing [E_o (acid) = + 2.10 V, E_o (alkaline) = + 1.24 V].

Xenon(VIII) oxide. The slow action of sulfuric acid on xenonates, preferably Ba_2XeO_6, yields gaseous XeO_4, which can be condensed at – 196 °C as a pale yellow solid and purified by careful sublimation at – 70 °C. The melting and boiling points of the compound are unknown. The vapor pressure at – 35 °C is 0.4 kPa and at 0 °C, 3.3 kPa. Xenon (VIII) oxide is highly unstable (ΔH_f 642.5 kJ/mol) and extremely explosive. Even at – 40 °C, it can explode unexpectedly. The XeO_4 molecule is tetrahedral and has a Xe – O bond length of 173.6 pm.

Aqueous solutions of xenon (VIII) can be obtained by disproportionation of xenate (VI) or by passing ozone through dilute alkaline solutions of XeO_3. Stable, insoluble perxenate salts such as $Na_4XeO_6 \cdot 8\,H_2O$, $Na_4XeO_6 \cdot 6\,H_2O$, or $Ba_2XeO_6 \cdot 1.5\,H_2O$ can be precipitated. The barium salt can also be obtained by oxidizing XeO_3 with ozone in a solution of barium hydroxide. Perxenate solutions are strong oxidizing agents. They are alkaline due to hydrolysis:

$$XeO_6^{4-} + H_2O \rightarrow HXeO_6^{3-} + OH^-$$

Apart from $H_2XeO_6^{2-}$, the predominant species in solution is $HXeO_6^{3-}$. Free perxenic acid cannot be isolated because it readily loses O_2, forming xenic (IV) acid.

Xenon oxide difluoride, $XeOF_2$, is synthesized by careful hydrolysis of XeF_4 at – 80 °C. It is a pale yellow solid that is metastable up to ca. – 25 °C.

Xenon dioxide difluoride, XeO_2F_2, and *xenon dioxide tetrafluoride,* XeO_2F_4, can be prepared by careful hydrolysis of XeF_6, by reaction of SiO_2 with XeF_6, or by comproportionation of XeF_6 with XeO_3. The former forms pale yellow crystals that are sensitive to hydrolysis, while the latter is a colorless, readily hydrolyzed liquid.

The oxide fluorides of octavalent xenon are highly unstable. The reaction of XeO_4 with XeF_6 affords XeO_3F_2 and $XeOF_4$; however, the latter has only been detected by mass spectroscopy. Thus, apart from the stable perxenates, the + 8 oxidation state of xenon is not readily accessible.

Other Xenon Compounds. The synthesis of a compound with a xenon – nitrogen bond was achieved in 1973. The reaction of XeF_2 with $HN(SO_2F)_2$ in CF_2Cl_2 gave $FXeN(SO_2F)_2$. The unstable compound $Xe(CF_3)_2$ has been reported to be formed by the action of CF_3 radicals on xenon [141]. The presence of a xenon – carbon bond in the $[C_6F_5Xe]^+$ ion has been proved by an X-ray structural analysis on $[CH_3CN - Xe - C_6F_5]^+$. Species of this type are obtained by reacting XeF_2 with $B(C_6F_5)_3$ at – 40 °C in a noncoordinating solvent [142].

2.2.4. Radon Compounds

Since the first ionization energy of radon is lower than that of xenon (see Table 2), it should be the most reactive noble gas. However, ^{222}Rn has a half-life of 3.82 d and is an intensive β-emitter, so that investigations of its chemistry are extremely difficult and can only be performed as tracer experiments. Radon(II) fluoride, RnF_2, is formed by direct fluorination of radon or through reaction with fluorinating agents such as O_2F_2, KrF_2, and ClF_3. Since the resulting radon compound sublimes only at 230 – 250 °C, it is assumed that radon fluorides are ionic (e.g., $Rn_2^+F_2^{2-}$). Cationic radon (probably RnF^+ or Rn^{2+}) has been detected in $C_2F_3Cl_3$ solution by ion exchange on a dry cation-exchange resin [143]. The hydrolysis of RnF_2 affords elemental radon. The fluorination of radon in BrF_5 as solvent in the presence of NiF_2 as catalyst at 250 °C gives a higher radon fluoride (RnF_4 or RnF_6), hydrolysis of which affords RnO_3 [144]. Like xenon, radon forms complex salts, which presumably have the general formula $RnF^+MF_6^-$ (M = Sb, Bi).

2.2.5. Molecular Structures of Noble Gas Compounds

The structures of the fluorides, oxyfluorides, and oxides of xenon follow the rules of the valence shell electron pair repulsion model (VSEPR) [145]. When the lone pairs are taken into account, XeF_2, $XeOF_2$, and XeO_2F_2 have trigonal bipyramidal structures with a linear F – Xe – F axis in the gas phase. In XeF_4 and its oxyfluorides, the four fluorine atoms occupy equatorial positions, while the electron lone pairs or oxygen atoms occupy the axial positions of the octahedral structure.

The structure of XeF_6 has been the subject of controversy [146]. The structure of monomeric XeF_6 in the gas phase is almost certainly not octahedral. Most likely it is a structure in which the nonbonding electron pair occupies an edge or vertex of the octahedron, distorting the structure. Since the structure is highly fluxional, the atoms around the xenon atom can undergo rapid rearrangement, so that on average the xenon atom is almost spherically surrounded (see Fig. 8 A) [147].

The structures in solution and in the solid state are shown in Figures 8 B and 8 C, respectively. The reaction of binary xenon fluorides with fluoride acceptors gives cations of the type XeF^+ or $Xe_2F_3^+$. Their salts often do not have simple ionic structures; in many cases fluoride bridging between the ions occurs, as exemplified by the structure of $XeF \cdot RuF_6$ (Fig. 9 A) [148]. Figure 9 B shows the crystal structure of a covalent oxygen-bonded derivative of XeF_2 [149].

Figure 8. Molecular structure of XeF_6 [147]
A) In the gas phase: dynamic, distorted octahedral; B) In solution: In nonbridging solvents (CF_2Cl_2, CF_3Cl, SO_2ClF, F_5SOSF_5), XeF_6 forms Xe_4F_{24} tetramers by fluoride bridging, and perhaps also through weak Xe – Xe interactions. The 24 F atoms are magnetically equivalent, suggesting that they are involved in a rearrangement process; C) In the crystal: The tetrameric Xe_4F_{24} units are "frozen" in the solid state and are best described as $(XeF_5^+F^-)_4$

Figure 9. Crystal structures of xenon compounds
A) $[XeF^+][RuF_6^-]$; B) $Xe(OSeF_5)_2$

2.2.6. Noble Gas Clathrate Compounds

Clathrate compounds are nonstoichiometric compounds in which noble gas atoms are held by van der Waals forces in the cavities in the crystal lattice of a host substance [150–152]. Host molecules include water, heavy water, hydroquinone, and phenols. The stability of the clathrate compounds increases with increasing polarizibality of the noble gas atoms; helium does not form clathrates. Characteristic data for some noble gas clathrates is listed in Tables 12 and 13 [120]. The hydroquinone clathrates of krypton and xenon are stable in air and undergo no change when powdered. When the hydroquinone framework is destroyed by solvents such as water, methanol, or ether, the noble gases are released violently. The clathrates also decompose upon heating to 130 °C. The hydroquinone clathrates can be stabilized by irradiation with X-rays [153].

The structures of the clathrates have been the subject of numerous investigations. Figure 10 shows a section of the hydroquinone cage structure with the formula $3\,C_6H_4(OH)_2$ [154]. Hydroquinone clathrates have been used for the purification and storage of the heavier noble gases. The clathrates of ^{85}Kr and ^{133}Xe are among the safest β- and γ-sources, respectively. Clathration of ^{85}Kr has been suggested as a method for trapping and storing radioactive fission gases [155].

Figure 10. Mode of cage formation of hydroquinone molecules
The hydroxyl groups are arranged in hydrogen-bonded hexagons. The longer lines connecting the hexagons denote the O – O axis and the benzene ring of the hydroquinone molecule

3. Occurrence and Availability

Helium is the second most abundant element in the universe after hydrogen and accounts for more than 25 mol % of the total cosmic material. In contrast, the other noble gases, particularly the lighter ones, are rare in the solar system.

3.1. Terrestrial Occurrence

The content of noble gases in the atmosphere is listed in Table 14. The composition of the atmosphere with respect to the noble gases has presumably been constant for the last 10^9 years and will remain so for the foreseeable future; only the content of argon is slowly increasing. There

Table 12. Some thermodynamic properties of noble gas hydrates and deuterohydrates with the theoretical composition $8\,X \cdot 46\,H_2O$ or $8\,X \cdot 46\,D_2O$ (X = noble gas) [109] [a]

Noble gas	Composition (found)	Dissociation pressure at 0 °C, MPa	Decomposition temperature at 100 kPa	Enthalpy of formation (kJ/mol) from gaseous noble gas (101.3 kPa) and ice	H_2O_{liq} or D_2O_{liq}

Rn	$(0.06 – 18) \times 10^{-23}$		
Total	0.932443	100.00	100.00

are no mechanisms known that bind noble gases. The small amounts isolated from the atmosphere are eventually released to the atmosphere. Although, with the exception of argon, the noble gases are only trace components of the atmosphere, they are present in almost inexhaustible quantities (He, 3.68×10^9 t; Ne, 6.46×10^{10} t; Ar, 6.79×10^{13} t; Kr, 1.59×10^{10} t; Xe, 1.97×10^9 t).

Air layers close to the ground, particularly those above extensive water bodies, have lower contents, especially of the more soluble, heavy noble gases, than the free atmosphere [156]. For the same reason, air dissolved in rain, rivers, seawater, groundwater, and in the bodily fluids of animals and plants is enriched in the heavier noble gases relative to the free atmosphere. The composition of the atmospheric noble gas mixture is constant up to an altitude of 59 km, above which the content of helium and neon increases while that of the heavier noble gases decreases. Helium and hydrogen are the major components of the thermosphere and ionosphere between 300 and 600 km.

Most terrestrial helium is generated by α-decay of uranium and thorium in the earth. A stationary equilibrium exists between helium gen-

erated in the earth's crust, helium released from the oceans [157], helium captured from the solar wind, and that which escapes to space from the atmosphere. The loss of helium is estimated at 5×10^8 t/a, about 50 % of the annual world requirement [158]. The total terrestrial inventory of helium (atmosphere, hydrosphere, and lithosphere) is estimated to be 900×10^9 t [159]. The isotopic ratio $^3He/^4He$ of terrestrial helium is ca. 10^{-6}. Therefore, air is uninteresting as a source of ^3He, and this isotope is synthesized by the nuclear reaction $^6Li\ (n, \alpha) \rightarrow {}^3He\ (\beta)$.

Air is the only source for the industrial production of neon, argon, krypton, and xenon. These gases, and sometimes also helium, are byproducts of air rectification and ammonia synthesis. Tetrafluoromethane, which is present in the atmosphere in trace amounts, has similar thermodynamic properties to krypton and is therefore concentrated in high-purity krypton, in which it was first detected in 1974 [160].

Natural Gas. Natural gas contains varying amounts of helium, ranging from negligible to over 0.8 mol %. Natural gas that contains > 0.3 mol % He is termed helium-rich. Helium contents of natural gases are listed in Table 15 [161–163]. The occurrence of helium in natural gas depends on the presence of particular geological conditions. First, the country rock and sedimentary rocks must have a high content of uranium and thorium and overlying porous rock to act as a gas reservoir. This gas reservoir must in turn be covered by a gas-tight, tectonically undisturbed layer. The helium is presumably carried into the reservoir by nitrogen and methane from neighboring oil fields or is desorbed by convection cells in hydrothermal fields. The helium content increases with the geological age of the formation. Most of the helium-containing fields lie at a depth of about 2500 m. It is believed that, independent of temperature and pressure, above a critical depth of 2100 m insufficient coverage is present to retain helium reserves [164].

The economically exploited helium reserves are concentrated in the United States (see Table 16 [165]). Most of them are clustered in the midcontinent and Rocky Mountain regions, including Cliffside Field, Texas; Hugoton Field, Kansas; Keyes Field, Oklahoma; Panhandle Field, Kansas, Oklahoma, Texas; and Tip Top Field, Wyoming. Total U.S. helium resources in natural gas are estimated by DOI at 1.2×10^{10} m^3. Notable helium fields outside the United States are Worsley Field, Alberta, Canada; Hassi R'Mel Field, Algeria; Orenburg Field, former Soviet Union; Sichuan Field, China; and Ostrow Field, Poland.

Table 16. World helium resources as of January 1996 (in 10^6 m^3) [165]

Country of region	$m^3 \times 10^6$	Share, %
United States		
Stored in Cliffside field	950	
Helium in helium-rich natural gas	5800	
Helium in helium-lean gas	5100	
Total (U.S.)	11 850	43.5
Former Soviet Union	8900	32.7
Algeria	2000	7.3
Canada	2000	7.3
China	1000	3.7
Poland	800	2.9
Netherlands	672	2.5

The content of the other noble gases in natural gas varies. The concentrations of argon, krypton, and xenon, relative to the accompanying nitrogen, are mostly lower than in air. Xenon from natural gas is enriched in the lighter isotopes compared to atmospheric xenon.

U.S. Helium Act Amendment. Helium is lost when natural gas is burned. These losses amounted to ca. 2×10^9 mol in the United States in 1972. Due to its rareness and use in certain strategically important applications, helium has been classified as a strategic resource by the U.S. Government. To ensure that U.S. helium requirements would be met by helium from natural gas up to and beyond the year 2000, the Helium Conservation Programme was introduced in 1960. This planned the extraction of ca. 7.5×10^{10} mol of helium from natural gas in the form of 70 % raw helium by 1986. The helium was stored in empty gas fields. The resulting costs were supposed to be covered by the sale of pure helium by the U.S. Bureau of Mines. The Bureau signed 22-year contracts with four private firms, which thereupon built helium extraction plants and together sold 3.5×10^9 mol of helium to the Bureau at a fixed price of \$ 28/kmol. By 1973, ca. 4.8×10^{10} mol of helium had been stored at Cliffside Field. Because of increasing deficits caused by private companies offering lower prices, the government cancelled the entire program under the announcement, that "the purpose of Helium Act Amendment has been accomplished."

In the mid-1970s, the Bureau of Mines began accepting privately owned crude helium for storage in the Cliffside gas field under long-term contracts. This privately owned crude helium is returned to owners as needed for purification to supply private demand. For example, during 1996, 35×10^6 m^3 of private helium was delivered to the storage system, and 20.6×10^6 m^3 was withdrawn. Then, in 1996 helium operations were transferred to the Bureau of Land Management (BLM) after the Bureau of Mines was closed. In October the *Helium Privatization Act* was signed. The legislation specifically calls for the Federal Government to exit the helium business, to begin selling its crude helium reserves by or before 2005, and to complete those sales by 2015. A Helium Reserve Committee presently is charged with estimating the effect of the sale of federal helium reserves on market and industry [166].

Hot Springs. Many hot springs in regions of current or former volcanic activity are rich in helium and neon. They contain up to 10 % helium, 1.2 % neon, as well as argon, some krypton, xenon, and traces of radon. The Ne/N_2 ratio is generally lower than that of air. Gases in the highly concentrated thermal brines of Ruhrkarbon (Central Europe) contain 10 – 15 vol % methane, 10 – 22 % carbon dioxide, 60 – 70 % nitrogen, 4 – 5 % helium, smaller amounts of neon, argon and krypton, and some radon. The average rate of gas production of these sources is ca. 1 kmol/d. Nitrogen-rich, noble-gas-containing gases are also found in coal mines. The gas quantities produced are small, typically 5 mol/h. These pit gases contain only traces of noble gases, which originated mostly from air dissolved in the sap of the plants from which the coal was formed.

Minerals. Because of the wide distribution of α-emitting isotopes, numerous minerals and rocks, particularly primitive rocks, contain helium. High helium contents (mmol He/kg) have been found in thorianite (150 – 470), cleveite (35 – 350), monazite (35 – 110), broeggerite (45), fergusonite (45 – 80), and pitchblende (ca. 12). Some minerals contain more helium than can be accounted for by their content of radioactive elements, for example, gadolinite (up to 110), beryl (up to 0.5), and sylvine (up to 2.5×10^{-4}). Argon occurs as an accompanying element in all potassium minerals. The heavy noble gases are rare in terrestrial minerals and occur in extremely small amounts. For example, a xenon content between 4×10^{-8} and 5×10^{-9} mmol/kg has been found in granite. In

comparison to atmospheric xenon, xenon in minerals is enriched in the heavier isotopes.

3.2. Occurrence of Radioactive Isotopes

A new source for stable and unstable isotopes of krypton and xenon are nuclear reactors and nuclear fuel reprocessing plants. Krypton isotopes with mass numbers 83 – 86 and xenon isotopes with mass numbers 131 – 136 accumulate as fission products in fuel rods at a rate of ca. 0.01 mol/h Kr and ca. 0.1 mol/h Xe per 1000 MW. They are released when the fuel rods are reprocessed [167]. Of the isotopes formed, it is mainly ^{85}Kr (half-life 10.86 a) that poses a radiological hazard. The others are short-lived nuclides with half-lives of at most a few days. The noble gas content of 1 t of fuel after a burnup of 33 GW · d/t and a cooling time of one year is 1 3 Xe and 0.13 Kr, of which 0.6 % is ^{85}Kr and the rest stable isotopes [168].

The noble gases are distributed rapidly in the entire atmosphere; apart from their low solubility in the oceans, they have no sinks. The ^{85}Kr activity in the atmosphere has been monitored since 1965. Measuring stations are located at Freiburg (FRG), Cracow (Poland), and Miami (USA). A steady increase in atmospheric ^{85}Kr concentration on a global scale is evident in Figure 11. The rate of increase is about 25 mBq/m^3 per year (ca. 3 %). The ground level in the northern hemisphere is, however, small, and amounted to 1.3 Bq/m^3 of air in 1998 [169].

The naturally occurring isotopes of radon are short-lived intermediates in the radioactive series of uranium, thorium, and actinium and are steadily generated and in decay. After plutonium, radon is the rarest element in the earth's crust with an estimated abundance of 6.2×10^{-16}%. Traces of radon are found in all radioactive material, particularly minerals. Radon readily escapes from the sites where it was formed and is disseminated in water and air. The concentration of radon, which is mainly ^{222}Rn, in lower atmosphere layers is 2 – 20 Bq/m^3, and in potable water 1 – 10 Bq/L with a maximum of up to 200 Bq/L. High radon concentrations are observed in spring waters near radioactive deposits such as those at Hot Springs, Arkansas or in the air of poorly ventilated mining tunnels.

The release of radon increases with the formation of surface fissures during geological events such as earthquakes and volcanic eruptions. Therefore, radon is permanently monitored in seismic regions as a useful instrument to forecast earthquakes. An activity estimated at 1.1×10^{17} Bq of radon was released during the eruption of the Mount St. Helens volcano in 1980.

3.3. Lunar and Solar Occurrence

Moondust and gas-rich meteorites contain relatively large amounts of hydrogen and noble gases. The gases, which apparently were adsorbed from the solar wind, are found mostly in thin layers on the surfaces of the minerals. Typical gas contents of moon dust in mmol/kg are: hydrogen, 45; helium, 9; neon, 0.09; argon, 0.02; krypton, 9×10^{-6}; and xenon, 4.5×10^{-6}. Moon rock that has not been loaded by the solar wind also contains small amounts of noble gases [171–173].

The relative abundances of the noble gases with respect to one another and the distribution of abundances of the isotopes of the individual gases vary according to origin. These variations allow conclusions to be made about the origin of the elements and, therefore, the evolution of the solar system. Thus, for example, investigation of the solar-wind noble gases in moon dust has given accurate information on the abundances of the noble gases in the sun. The xenon isotopes are particularly important in these studies because their mode of formation is well known and they can be determined quantitatively with high accuracy (xenology) [173].

4. Extraction and Isolation

The sources for industrial production of noble gases are nowadays exclusively air and natural gas, or else residual gases from processes where air or air products and/or natural gas are processed, such as ammonia synthesis. The concentrations of the noble gases in these sources are low, which has two consequences as far as their separation is concerned:

1) The reversible, i.e., minimum, specific work for separating a unit quantity of noble gas is relatively high compared with other industrial separations. It is shown in Figure 12 for two different sets of conditions, namely for infinitely large gas throughput corresponding to Equation (1) and for complete separation of the noble gases, i.e., 100 % yield, in accordance with Equation (2).

$$W_{\mathrm{rev},\infty} = -RT_{\mathrm{a}} \ln x_0 \qquad (1)$$

$$W_{\mathrm{rev},100} = -RT_{\mathrm{a}} \left[\ln x_0 + \frac{1 - x_0}{x_0} \ln (1 - x_0) \right] \qquad (2)$$

where T_{a} is ambient temperature.

Figure 12. Reversible work for separation of ideal mixtures as functions of initial concentration x_0
a) For infinitely large gas throughput (Eq. 1); b) For complete separation of the noble gases (Eq. 2)

2) The actual separation work is much higher than the reversible work and increases relatively sharply with falling initial concentration of the component to be extracted because of the wasteful simultaneous treatment of large quantities of accompanying components. Because of these energy considerations and because of the high specific capital costs involved with low initial concentrations the noble gases are always produced as byproducts from fractionation plants for oxygen and ammonia synthesis residual gas, where they have already become enriched during the separation of the main products. Table 17 shows the concentrations in various feed gases and the quantities obtainable in the various processes.

The demand for noble gases, especially for argon, krypton and xenon, has risen continuously over the years. More and more plants for fractionating air are therefore being fitted with auxiliary equipment for separating noble gases.

Table 17. Concentration and quantities of noble gases in various sources

Gas	Concentration (mL/m^3) in				Potential production rate, mol/h

4.1. Isolation From Air

Separation of noble gases from air is described here based on the example of an oxygen plant using the low-pressure process. A schematic of the process is shown in Figure 13. Atmospheric air is compressed to approximately 6 bar and freed from H_2O, CO_2, and hydrocarbons in molecular sieve adsorbers. The majority of the air is cooled to almost dew-point temperature in countercurrent flow to nitrogen and oxygen and fed to the bottom of the medium-pressure column. After the molecular sieve adsorbers a smaller quantity of the air is compressed in a booster, which is coupled directly to the expansion turbine, and is also cooled in countercurrent flow to nitrogen and oxygen; it is then expanded in an expansion turbine to the pressure of the low pressure column and injected into it.

4.1.1. Helium and Neon

The concentration of helium in air is ca. 5 mol ppm and that of neon is 20 mol ppm. Air represents the only economically exploitable source of neon, but helium is only extracted from air in exceptional cases as many natural gases contain helium in concentrations which are a hundred to a thousand times higher.

In the distillative fractionation of air as shown in Figure 13, the noble gases helium and neon become concentrated in the reflux condenser of the medium-pressure column together with the hydrogen contained in the air. In noble gas production there is an enrichment of up to about a thousand times the input value. Further concentration of the helium and neon to ca. 50 mol % is carried out in a small secondary column whose overhead condenser is cooled at ca. 80 K with evaporating liquid nitrogen. A fraction can be drawn from the top of this column with a typical composition of 11 mol % He, 35 mol % Ne, 5 mol % H_2 and 49 mol % N_2 with a noble gas yield of over 90 %. Further separation of this fraction is discussed below.

Helium – Neon Separation by Condensation. An older publication [174] describes a condensation method for separating helium and neon in which a helium refrigerator is required for liquefying the neon. In the Linde process shown in Figure 14 (see page 26), the helium refrigerator is replaced by an Ne – He cryoprocess with nitrogen precooling and a Joule – Thomson valve. The hydrogen and nitrogen components are removed from the crude gas before the low-temperature separation is performed. Hydrogen is converted catalytically to water on a noble metal catalyst (a_1) with the addition of oxygen. The gas, which is now saturated with moisture, is transferred to the gasholder (b_1), from where it is transferred to the high-pressure reservoir (b_2) by the compressor (c_1) for intermediate storage. Even in large air fractionation plants the crude He – Ne flow is only ca. 0.1 mol/s and is therefore too small for a continuously-operated condensation system operating on an industrial scale. The intermediate storage allows the subsequent process steps to be carried out in batches.

The crude gas from the high-pressure reservoir (b_2) is expanded to about 30 bar, freed from water by adsorption at room temperature in the drier (d_1), which is filled with molecular sieves, and then cooled to ca. 66 K in the heat exchangers (e_1) and (e_2). This condenses most of the nitrogen contained in the crude gas. The liquid phase is separated from the gaseous phase in the separator (f_1). The remainder of the nitrogen in the gas phase (< 2 mol %) is retained by the silica-gel-filled adsorber (d_2) to give a mixture

of approximately 76 mol % neon and 24 mol % helium, which, after it has been heated to room temperature and expanded to ambient pressure, is transferred to the compressor (c_2).

The liquid phase from the nitrogen separator (f_1) is expanded to almost ambient pressure in the second separator (f_2), and the majority of the neon and helium dissolved in the liquid is released; it is returned to the gasholder (b_1) after heating to room temperature. After its pressure has been reduced to about 0.2 bar, the remaining condensate from the second separator (f_2) is vaporized together with the liquid nitrogen supplied as refrigerant, heated to room temperature, and released to atmosphere through the vacuum pump (c_3).

The compressor (c_2) compresses the helium – neon mixture to ca. 180 bar. The gas stream is cooled to about 80 K in the heat exchanger (e_3) and the nitrogen evaporator (e_4) and then further to about 50 K in the heat exchanger (e_5). After expansion to ca. 25 bar the majority of the neon condenses in the heat exchanger (e_6) and the heat of condensation is dissipated by pure neon evaporating at virtually ambient pressure. The condensate is separated from the gas phase in the separator (f_3). The liquid is then expanded to ca. 1.5 bar. The majority of the dissolved helium passes into the gas phase. The liquid neon is then freed from the remaining helium in the stripping column (g_1). After evaporation in the heat exchanger (e_6) the purified neon is heated to room temperature again. The diaphragm compressor (c_4) transfers the extracted neon, with an impurity level of less than 10 mol ppm, to the high-pressure reservoir (b_3).

The neon-rich gas leaving the top of the column (g_1) is heated to room temperature in the heat exchangers (e_5) and (e_3) and is fed to the suction side of the He – Ne compressor (c_2).

The gas leaving the separator (f_3) contains ca. 85 % helium and 15 % neon. This gas flows

through heat exchangers (e_5), (e_3), (e_1) and (e_7) and the neon adsorber (d_3), which contains activated carbon. After warming to room temperature, helium with an impurity level of less than 10 mol ppm can be transferred to the high-pressure reservoir (b_4) by the diaphragm compressor (c_5).

The gas produced when regenerating the adsorbers (d_2) and (d_3) is transferred to the gasholder (b_1). This process achieves a yield of helium and neon of more than 98 %.

The process described above is carried out industrially in a variety of ways. The heat exchangers and adsorbers were arranged as shown in Figure 14 for practical reasons. In principle the heat exchangers (e_1) and (e_3) can form one structural unit, (e_4) can be accommodated in the nitrogen bath (i_1), and the neon adsorber (d_3) can be positioned directly after the heat exchanger (e_5).

Figure 15. Leyarovski process for production of helium and neon
a) Freezing heat exchanger; b) High-pressure reservoir; c) Compressor; d) Adsorber; e) Heat exchanger; f) Separator

Figure 15 shows a process [175] which dispenses with catalytic hydrogen conversion. Nitrogen is adsorbed at 80 K and neon condenses at approximately 30 K under a pressure of 10 bar. After expansion to ambient pressure the dissolved components helium and hydrogen escape, with the result that neon can be obtained with an impurity level of less than 1000 mol ppm. The gas produced during expansion is released to atmosphere so the neon yield is only about 90 %. The fraction which is noncondensible at 30 K and 10 bar contains 80 mol % helium. After adsorption of neon on active carbon at 30 K, helium is produced with a purity of 99.8 mol %. Liquid nitrogen and a closed neon circuit with nitrogen precooling, countercurrent heat exchanger, and Joule–Thomson valve are used for cooling.

Helium – Neon Separation by Absorption. The solubility of neon in liquid nitrogen is higher than that of helium. A laboratory apparatus is described in [176] with which neon is washed out of an Ne – He – N_2 mixture with pure liquid nitrogen. This produces a gas containing ca. 90 mol % He, 3 mol % Ne, and 7 mol % N_2 and a liquid with 0.2 mol % He, 2.8 mol % Ne, and 97 mol % N_2. The additional process for preparation of pure helium and neon is only outlined.

Helium – Neon Separation by Adsorption. Neon and helium can be separated from an Ne – He – N_2 mixture by condensation and multistage adsorption by using the process shown in Figure 16 [177]. The mixture is cooled to 67 K at ca. 5 bar to condense the nitrogen. The subsequent N_2 adsorption of the residual nitrogen from the gas is performed at 77 K. Neon adsorption is carried out in two stages at 67 K. In the first stage neon is adsorbed at 5 bar, which increases the purity of the helium to 99.9 mol %. After the adsorbent is exhausted the pressure in this first adsorption stage is lowered to 3 bar at low temperature, and the gas produced is transferred to a second stage for renewed neon adsorption, again producing pure helium. By lowering the pressure in the second adsorption stage to 2 bar at low temperature ca. 8 % of the total neon is produced with a purity of 98.5 mol %. Pure neon at 99.98 mol % is liberated during the final expansion in the two adsorption stages to ambient pressure and indirect heating with air at 470 K. The neon yield is 82 % and that of helium 90 %. All adsorption stages are fitted with two reversible units.

Figure 16. Leyarovski adsorption process for producing helium and neon
c) Compressor; d_1) N_2 adsorber; d_2) Ne adsorber, first stage; d_3) Ne adsorber, second stage; e) Heat exchanger; f) Separator

A more recent adsorptive method operates with a pressure-swing system at 80 K and is claimed to produce neon with impurities of less than 100 mol ppm [178].

4.1.2. Argon

The volatility of argon lies between those of nitrogen and oxygen; for example, the ratio of the volatilities of nitrogen, argon, and oxygen in the low-pressure column with little nitrogen and 15 % argon in the vapor is 3.6: 1.5: 1, cf. the mass balance in Figure 13. As a result of this equilibrium behavior, when the usual reflux ratios are applied in the low-pressure column (where pure oxygen is produced) the argon accumulates above and below the crude oxygen feed point. In the lower part of the column, argon concentrations of up to 15 % in the vapor phase can be attained.

This argon maximum– or somewhat below it to reduce the nitrogen content–is the appropriate point for drawing off the so-called argon side stream, which is then rectified in the argon auxiliary column (crude argon column, see Fig. 13). Crude argon, with 3 – 5 % O_2 and up to 1 % N_2, is drawn off at the top of this column.

Energy Balance and Argon Yield. In spite of the high liquid/vapor ratio in the column the separation of crude argon theoretically requires no additional energy. This is because the addition of the auxiliary column to the system reduces the amount of the materials processed in the low-pressure column. In practice, however, low-pressure columns with argon extraction have more trays than those without argon extraction and consequently exhibit higher pressure losses; they therefore require a higher initial feed air pressure. Against this, however, can be set the higher oxygen yield in columns with argon extraction, so the "extra" energy is not significant.

Argon yield. High argon yields require two loss terms to be minimized: the equilibrium loss that would occur if the argon content in the nitrogen being drawn off were in equilibrium with the argon content of the nitrogen reflux, and the rectification loss caused by incomplete approach to equilibrium during rectification.

Minimization of the equilibrium loss requires a small argon content in the reflux nitrogen. In air fractionation plants with oxygen as main product, no better level of purity than about 1 % O_2 in the reflux nitrogen is required. This is normally obtained with a liquid vapor ratio in the medium-pressure column of ca. 0.53. The equilibrium constant of argon at 6 bar is 0.54 with nitrogen as opposed to 0.65 in equilibrium with air, so for a liquid/vapor ratio of 0.53 there is only slow upward enrichment of the argon. Only

fairly large reflux ratios and low oxygen content in the reflux nitrogen lead to smaller argon contents. Compromises are required for the sake of a good oxygen yield.

However, a high liquid/vapor ratio in the medium-pressure column means less reflux nitrogen and therefore a lower liquid/vapor ratio in the nitrogen section of the low-pressure column. This eventually leads to increasing disruption of the argon equilibrium at the top of the low-pressure column and so to increasing rectification loss. The total amount of argon produced from the feed air quantity, i.e., the argon yield, is mainly dependent on the turbine flow to the low-pressure column (see Fig. 17).

Purification of Crude Argon. After the crude-argon column the crude argon passes through the following process stages:

1) Crude argon is compressed to 4 – 6 bar after heating to ambient temperature.
2) After addition of hydrogen the oxygen is reduced to a residual content of less than 1 vol ppm in the deoxo, a container filled with noble metal catalyst. If the crude argon has a fairly high oxygen content it must be recycled to cool the adiabatically operated deoxo.
3) The oxygen-free crude argon is dried adsorptively at ambient temperature.
4) In the subsequent pure-argon distillation column, which is heated with medium-pressure nitrogen (or crude argon, with recovery of the excess hydrogen) and is cooled with liquid nitrogen, the top product is nitrogen, the excess hydrogen and some argon, while argon with 99.9999 % purity is drawn off at the bottom, normally in liquid form for ease of storage and transport. It is necessary to ensure, by using a sufficiently high pressure ($\geq$ 2 bar) for the nitrogen evaporating in the overhead condenser, that the condensing argon (triple point 84 K) does not solidify.

In principle, it is also possible to produce a crude argon intermediate product with an oxygen content of 1 vol ppm by complete rectification of the side stream in the auxiliary column. This, however, requires a very large number of trays. To ensure that condensation is still possible by cooling with evaporating crude oxygen, the pressure loss in the argon auxiliary column must not be greater than, for example, in a tray column containing about 50 sieve trays. This is possible with a column which has random or structured packing for the separating stages instead of sieve trays. This arrangement (see Fig. 18) makes the addition of hydrogen to the crude argon and subsequent combustion of oxygen in a deoxo unnecessary [179].

4.1.3. Krypton and Xenon

Because of their low volatilities, krypton and xenon collect in the oxygen bath of the main condenser. In plants with gaseous oxygen take-off without krypton–xenon recovery the krypton concentration is approximately 50 mL/m^3 (50 vol ppm) in gaseous oxygen. To recover the noble gases, part of the liquid oxygen from the oxygen bath is fed to the krypton – xenon concentration column, where a krypton – xenon concentrate with ca. 0.3 % Kr + Xe is produced.

Further concentration of krypton and xenon should not result in any great loss of yield. For this purpose, extra trays (krypton trays) are installed between the main condenser and the take-off point for gaseous oxygen product (see Fig. 13) to wash back krypton and xenon by oxygen reflux.

Undesirably high hydrocarbon contents must be avoided at all points in the system. The methane level in the main condenser can be regulated by the quantity of feed to the concentration column. The methane level is normally kept to a few hundred vol ppm CH_4, i.e., well below the ignition limit of 5 % CH_4, to take account of the fact that higher concentrations could occur as a result of phase changes, local concentration, and plant stoppage. In the concentration column the content of methane and other hydrocarbons, for safety reasons, must not exceed 0.5 %.

The methane level in the main condenser can be reduced, albeit with loss of krypton, by feeding the oxygen vapor formed as top product of the concentration column directly into the product oxygen, instead of into the low-pressure column.

An effective additonal measure to reduce the methane level in the oxygen bath around the main condenser is to use a methane bypass column, which is installed in parallel to the krypton barrier trays and in which gaseous product oxygen is made. The methane level in the main condenser is lowered to about one-third, with negligible krypton losses, if the column is operated with a liquid/vapor ratio of 0.2 (between $k_{Kr} = 0.12$ and $k_{CH_4} = 0.30$).

Safety while concentrating the preconcentrate can be further increased by replacing the oxygen by argon before the concentration [180]. This step, which exploits the anomalous argon – oxygen equilibrium behavior, can be integrated particularly well, and without argon loss, in plants that are also intended for argon production.

Purification of the Krypton – Xenon Concentrate. In addition to krypton and xenon the krypton – xenon concentrate still contains oxygen (or argon), hydrocarbons, and possibly traces of other impurities, e.g., carbon dioxide.

The concentrate is, for example:

1) Brought to a pressure of 55 bar (supercritical) with a liquid pump and heated in a hot water heater to ambient temperature so that it can then be expanded again to 6 – 10 bar. Compression to a supercritical state is necessary on safety grounds, so that no dangerous enrichment of hydrocarbons can take place during the heating such as would be possible in an evaporating liquid;
2) Freed from hydrocarbons in a platinum contact furnace at 600 K;
3) Freed from carbon dioxide and water in an adsorber filled with molecular sieves;
4) Freed from oxygen and argon in a column at ca. 4 bar. The oxygen and argon stream is returned to the krypton – xenon concentration column. The increased pressure reduces the solidification of krypton and xenon.

The krypton – xenon mixture containing 10 – 50 % oxygen which is obtained at the column bottom is placed in intermediate storage and processed further, after another hydrocarbon combustion step, in a batch distillation process (Fig. 19). The crude krypton – xenon – oxygen mixture is condensed in a column, which is then heated at the sump and cooled at the top. At the top a small gas flow is drawn off which consists initially of almost pure oxygen and is returned to the first concentration stage. After this comes an oxygen – krypton mixture which is placed in intermediate storage, and finally pure krypton is obtained with less than 100 vol ppm impurities. When xenon also appears in the krypton the batch is finished and a krypton – xenon mixture predominantly consisting of xenon collects in the sump. This is freed from krypton in a further batch distillation process after removal of trace impurities in combustion furnaces and adsorbers. The residual gas is also collected here and is returned later to a suitable point in the process. Pure xenon with less than 100 vol ppm

impurity collects in the sump of this column. Because of the small quantities, the complicated procedure, and the laborious analysis, the production process for pure krypton and pure xenon is normally housed in a laboratory.

4.2. Helium Extraction from Natural Gases

Of the noble gases contained in natural gas, only helium is suitable for extraction [181]. The other noble gases are present in such small concentrations that they are not worth separating, but with a content of 0.005 – 8 % the helium offers a good source for helium production [182, 183]. Extraction of helium by itself is only viable at contents above 1 % [184], and it is only worth extracting helium at lower concentrations if other products are also obtained from the natural gas.

In industrial plants a crude helium stream is first separated from the natural gas. This is then followed by one or more purification stages if highly pure helium is required. The crude helium extraction and the purification systems are often interconnected by recycle streams.

4.2.1. Crude Helium Extraction

Crude helium is usually produced by partial condensation at low temperatures [185]. Increasing consideration has also recently been given to the membrane process, or to a combination of cryogenic and membrane processes.

4.2.1.1. Low-Temperature Fractionation

Partial condensation exploits the extremely low liquefaction temperature of helium. Natural gas is cooled in stages until practically all the components with the exception of helium have condensed. The residual gas phase is the crude helium product, with a helium concentration which is determined by the pressure and the lowest condensation temperature. Maximum helium concentrations of ca. 99 % can be reached at temperatures close to the melting point of nitrogen [181].

Figure 20. Behavior of helium during condensation of natural gas
D = vapor quantity, V = total quantity, F_{He} = dissolved helium, V_{He} = total helium

Figure 20 shows the temperature and pressure dependence of:

1) The equilibrium compositions of the liquid and vapor phases,

2) The ratio of vapor quantity to total quantity, and
3) The quantity of helium dissolved in the liquid as a percentage of the total quantity of helium

for natural gas from Keyes, Oklahoma (2.1 % He, 26.3 % N_2, 71.6 % CH_4 and heavier components [186]). Although the concentration of helium in the liquid phase of the natural gas is very low, the dissolved helium can reach a substantial proportion of the total quantity of helium contained in the natural gas because of the large quantity of condensate formed. In practice the dissolved helium is therefore recovered by stripping, rectification, or expansion of the condensate in stages, which substantially improves the helium yield [187].

Industrially, helium extraction is usually combined with other processing steps for natural gas, particularly with partial condensation. Helium separation then becomes a subprocess of a main process which determines the process structure and this naturally makes a significant improvement in the cost-effectiveness of the extraction process. Very often this is carried out during the separation of nitrogen from nitrogen-rich natural gases to improve the calorific value, because a high helium content is usually associated with a high nitrogen content [182].

In natural gas liquefaction, the helium collects during condensation in a gas residue, which can be readily concentrated and purified. The first stages of the gas treatment and partial condensation are also already performed during the extraction of ethane and heavier hydrocarbons from natural gas, thus relieving any subsequent helium separation of this task.

An important factor in all processes is the initial concentration of helium in the natural gas. With low helium concentrations great care has to be exercised in the recovery of the helium dissolved in the condensates in order to achieve good yields.

An important part is also played by the natural gas impurities, especially CO_2, H_2S, and heavy hydrocarbons. These components can solidify at low temperatures and lead to deposits. If their concentrations exceed certain limits they must therefore be removed before they enter a low-temperature section. Great efforts are made to use skilful process technology to pass the highest possible percentage of impurities safely through the system and to avoid preceding purification steps. It is, however, impossible to avoid removing the water vapor.

The required output pressure of the helium-free natural gas is the decisive factor determining the energy requirement of the system. If the treated natural gas can be delivered under reduced pressure, then the refrigerating requirements can sometimes be covered by the Joule–Thomson effect alone. In other cases additional refrigerating cycles or recompression of the natural gas is necessary.

A simple, but typical modern process for helium recovery combined with nitrogen removal from natural gas is shown in Figure 21. The clean natural gas is cooled against cold product streams in heat exchanger (a) and is fed to the bottom of the high-pressure column (b). The condenser (c) provides reflux for this column and for the low-pressure column (d). That part which is not condensable contains most of the helium. It is drawn from the crude helium separator (e) and leaves the plant as crude helium product after warming.

Figure 21. Nitrogen rejection and crude helium recovery from natural gas
a) Feed/product exchanger; b) High-pressure column; c) Reboiler/condenser; d) Low-pressure column; e) Crude helium separator; f) Feed subcooler; g) Residue pump; h) Reflux subcooler

The bottoms from the high-pressure column, having some of the nitrogen removed, form the feed stream for the low-pressure column (d), where the final nitrogen–methane separation is performed. The overhead is the nitrogen stream, which is rewarmed against the incoming feed stream. A reboiler in the bottom of the column

Figure 22. Schematic of a plant for recovery of helium from natural gas, with integrated separation of nitrogen, methane, and a C_{2+} fraction

provides a liquid, methane-rich residual product, which is pumped to an elevated pressure, vaporized and rewarmed against the incoming feed.

The reboiler duty in the low-pressure column necessary to provide a residue with low nitrogen content is provided by condensing nitrogen at the top of the high-pressure column. This is possible because of the different pressures of the two columns. The condensation temperature of nitrogen in the overhead of the high-pressure column (b) is higher than the boiling temperature of the methane-rich liquid in the low pressure column (d).

A significantly more complicated process is used in a plant in the United States [188]. The following products, besides a crude helium fraction, are recovered from the natural gas: a C_{2+} fraction, a methane sales gas, a fuel gas fraction, and a nitrogen fraction (Fig. 22). The composition of the feed gas and the products is given in Table 18.

Table 18. Composition of the feed gas and products for the plant in Figure

	Feed gas	NGL	Sales gas	Fuel gas	He	N_2
Composition, mol %						
Helium	0.50		0.01		56.94	0.17
Nitrogen	10.20		2.99	23.48	42.99	99.55
Methane	73.02	0.70	96.52	76.51	0.07	0.28
Ethane	6.94	41.21	0.47	0.01		
Propane	5.16	32.07	0.01			
C_{4+}	4.18	26.02				
Flow, kmol/h	2988	480.1	2019.4	299.1	25.4	164
Pressure, bar	44	9	8	8	27	1
Temperature, K	311	262	306	306	306	306
Gross wet calorific value, MJ/kmol	989.7	2154.5	852.7	670.2		

Pretreated natural gas is compressed to 50 bar in an expander booster compressor (a) and is cooled to 230 K by heat exchange with low-temperature propane and with cold products. The condensate is separated in the separator (b) and conveyed to the demethanizer (c).

After partial condensation, the gas from the separator (b) enters the nitrogen enrichment column (d), which operates at 31 bar. The bottom product from this column is pumped to 40 bar and partially vaporized, and the resulting phases are separated in the expander suction scrubber (e). Both phases are fed to the demethanizer (c) – the liquid phase after partial vaporization, the gas phase after expansion in the turbine (f). The liquid produced in the turbine serves as a reflux for the column.

The bottom product from the demethanizer (the C_{2+} fraction) and the top product (the sales gas, mainly methane), leaves the system, the top product having been warmed up again against the feed gas and the recycle stream.

The top product from column (d), enriched with nitrogen, is fed to a double column (g). After it has been subcooled, the bottom product from the lower, high-pressure section of the column forms the feed for the upper, low-pressure section of the column. The gaseous top product of the high-pressure column, in which almost all the helium has collected, and part of the top condensate are fed into the helium column (h) where the crude helium is concentrated to 57 % and, after being warmed up, leaves the system.

After subcooling, the bottom product from the helium column (h) serves as a reflux for the low-pressure section of the double column (g), from the top of which the nitrogen fraction is drawn off and discharged to the atmosphere after warming up. The bottom product is pumped to about 9 bar and, after warming up, used as fuel gas.

The necessary heating and cooling of the nitrogen enrichment column (d) is provided by a recycle with part of the sales gas via the recycle compressor (i).

4.2.1.2. Crude Helium Extraction by Permeation Processes

Also suitable for separating helium from natural gas are processes based on the principle of permeation. Gas permeation through homogeneous membranes occurs by solution – diffusion. The permeability coefficient is equal to the product of Henry's law constant S_i, and the diffusivity coefficient D_i, of component i in the membrane material. A membrane's ability to separate a gas mixture can be obtained from the ratio of the permeation coefficients: $\alpha_{ij} = P_i/P_j$, where α is the selectivity or separation factor of gaseous components i and j. Homogeneous membranes have a high permeability for helium compared to the remaining components of natural gas, i.e., nitrogen, methane, carbon dioxide and others (see Table 10; further literature in [189] and [190]).

The first applications of membranes for the extraction of helium date from 1958 when helium was extracted from natural gas by means of tubular silicate and quartz glass membranes. Commercial use of membrane processes for extracting hydrogen began in the early 1970s and since 1985 they have also been used for helium separation from natural gas for the production of crude helium [191].

The heart of a membrane process is the separation module. Commercially available separation modules contain either hollow fiber bundles (Permea, Ube) or spiral-wound gas permeation elements (Grace, Separex). For the structure of these modules see → Hydrogen, Chap. 5.5.2.

Figure 23 shows a schematic of a helium concentration process. In this case the two stages of the membrane system consists of a row of separators each containing a hollow fiber bundle physically similar to a shell and tube heat exchanger. The membrane is an aromatic polyimide polymer membrane with a membrane area of 9000 m^2 per m^3 of volume. The membrane works satisfactorily in the temperature range − 80 to + 150 °C and tolerates natural gas accompanying compounds such as water (up to saturation), hydrogen sulfide (up to 5 vol %) as well as C_{5+} (up to saturation). Table 19 gives some operating figures of the first stage of a membrane helium recovery system for helium-rich natural gas [192].

By their nature membrane processes are more suitable for coarse separation of helium from natural gas; i.e., it is not possible to achieve a high level of helium purity combined with a high helium yield in a simple membrane process. If this is required it is necessary to change to a system of several membrane process steps

Figure 23. Two-stage membrane helium recovery system [192]

connected in series. One or more compressor stations would then be needed between the process steps and for returning residual gases which are produced during the membrane process from retentates and permeates to be recycled. This would overextend the entire process and make it uneconomical. In such cases there is much to recommend a combination of cryo-process and membrane process, or of membrane process and pressure swing adsorption (PSA) process.

Table 19. Operating figures of the first stage of a membrane helium-recovery unit

	Feed	1st Stage permeate	Crude He
Pressure, bar	35	1.05	1.05
He recovery, %			95
Composition, mol %			
He	2.40	11.2	59.53
CO_2	0.07	0.3	0.76
Ar			
N_2	24.54	22.3	10.02
CH_4	72.71	66.1	29.68
C_{2+}	0.28	0.1	0.01

Several hybrid membrane – cryogenic or membrane – cryogenic – adsorption processes have been suggested [193]. The most advantageous seems to be the hybrid process with the following characteristics (Fig. 24). Helium-containing natural gas (ca. 2 % He, 26 % N_2, 64 % CH_4) at ca. 32 bar is cooled to ca. − 50 °C to condense all the heavier hydrocarbons. Then the gas is further cooled to ca. − 150 °C to condense all the methane and some of the nitrogen. The gas from these separation stages contains 30 – 35 vol % helium. This helium-rich stream is fed to the membrane system, in which a number of membrane stages can be configured to maximize the separation efficiency and to produce the desired 95 % stream. Any unrecovered helium is recycled to the cryogenic unit. To obtain grade A helium (purity 4.5), a PSA unit may be integrated. The process can be optimized by varying the helium content of the helium-enriched stream leaving the cryogenic stage and hence the membrane area to He content ratio. It is claimed that the power required by the hybrid process is only 54 % of that of a purely cryogenic process.

4.2.2. Purification of Helium

Besides adsorptive processes also cryogenic and chemical processes are used for the purification of crude helium. Different process steps are frequently linked with one another in case the required purity cannot be achieved in a single step.

Figure 25. Schematic of a typical four-adsorber PSA unit

4.2.2.1. Purification of Helium by Pressure Swing Adsorption

Helium is retained only weakly by adsorbents so it is easy to purify by adsorption processes. In principle this involves processes with thermal regeneration or pressure swing adsorption (PSA) processes. In processes with thermal regeneration heat is supplied to the process externally for desorption, but in PSA processes the regeneration is carried out without the supply of external heat, merely by pressure release and purging at low temperature. Generally, processes with thermal regeneration are confined to the removal of trace impurities or readily adsorbed components. At ambient temperature these processes are used for removing water and carbon dioxide, and at low temperatures also for removing, for example, traces of nitrogen, oxygen, neon, and hydrogen. With PSA systems it is possible to remove less readily adsorbed components at ambient temperature and even at quite high concentrations.

During the extraction of helium from natural gas the hydrocarbons and the majority of the nitrogen are separated in the low-temperature system. Nitrogen is virtually the only helium impurity requiring secondary purification in the PSA system. Zeolitic molecular sieve and narrow-pored activated carbon are suitable adsorbents for nitrogen. These adsorbents give final purities of 99.999 – 99.9999 vol % He without additional purification steps.

Pressure swing adsorption systems for helium purification are comparable in principle with systems for hydrogen purification; in this process helium behaves in a similar way to hydrogen (→ Hydrogen, Chap. 5.2.3.). Adsorption systems with four or less adsorber vessels are normally used because the feed gas flows to be processed are smaller than in the hydrogen systems (see Fig. 25). In such a system with 4 adsorbers the individual adsorbers pass cyclically through the following process steps: adsorption, pressure equalization with another adsorber, further pressure release in parallel flow to the adsorption step to output purge gas for another adsorber, counter-current pressure release to output tail gas, purging with decompression gas from another adsorber, pressure build-up by pressure equalization with yet another adsorber, and further pressure build-up to the adsorption pressure with helium product. A helium yield of about 80 % can be achieved with an adsorption pressure of 15 – 20 bar.

The tail gas produced in PSA processes still contains considerable quantities of helium so, unlike the procedure in the majority of hydrogen PSA systems, it is compressed again because of the substantially higher value of helium and re-

turned to the cryogenic unit, resulting in a helium yield of practically 100 % for the entire system.

In principle a PSA system can remove nitrogen contents of up to 50 vol % and produce ultrapure helium. The N_2 loading at the adsorption pressures normally used is virtually linear over a fairly large partial pressure range so the adsorber size only increases slightly with increasing N_2 concentration in the crude helium, while the helium yield falls with increasing adsorber size.

Due to the recycling of tail gas, the quantity of crude helium fed to the PSA system increases in inverse proportion to the helium yield of the PSA. The capital costs and the energy consumption for recompression of the tail gas to the cryogenic unit shows the same behavior. On economic grounds it has therefore been found that an N_2 content of 5 – 15 vol % in the crude helium to the PSA is the most cost-effective solution for combination with low-temperature separation.

4.2.2.2. Other Processes for Purification of Helium

Except for hydrogen, virtually all components can be separated from helium by pressure swing adsorption. Normally there is no hydrogen in helium, but if hydrogen is present, e.g., through the addition of industrial gases, then other processes have to be used.

Hydrogen is removed by catalytic combustion. The crude helium is mixed with air and the mixture is passed over a catalyst. If the resulting heat of reaction is too high then a recycle system can be used to reduce the hydrogen content in the feed gas to the reactor. The water formed is condensed out by cooling (provided that this is possible from the point of view of the partial pressures) and the remaining water can be separated together with the other impurities in a pressure swing adsorption system.

Purification processes based on hydride-forming metal alloys are also suitable for producing high-purity helium and for purification of the other noble gases. Noninert gas constituents (H_2O, CO_2, O_2, CO, C_mH_n) are combined on the surface of highly active getter alloys, or, as in the case of hydrogen, they diffuse into the metal lattice. When the partial pressure reaches the so-called hydride formation plateau the hydrogen is combined as metal hydride (→ Hydrogen, Chap. 9.3.1.2.).

Highly effective getter alloys consist of Ti, V, Fe, and Mn in varying molar ratios depending on the application; the H_2 partial pressure can be lowered to 5×10^{-6} bar by $TiV_{1.5}Fe_{0.4}Mn_{0.1}$. The gas flow is passed directly through the getter beds (pressure drop < 1 bar), which can be regenerated by raising the temperature (200 – 500 °C) or returned to the manufacturer after use (e.g., HWT, Germany). A helium purity of 6.0 (99.9999 vol %) is achieved; a purity of 7.0 can be attained if the gas is passed over a high-temperature getter bed at 350 – 450 °C, which allows practically no foreign gas constituents to pass. This results in an oxygen content, for example, which can no longer be detected by current analytical methods [194].

4.2.3. Example of a Complete Process

The two plants at Alfortville in France where nitrogen is separated from Groningen natural gas and helium is extracted are examples of plants which perform crude helium extraction as well as helium purification [195].

The helium content in the Groningen natural gas is relatively low compared with many natural gases in the United States or in Poland for which systems have also been built for helium extraction [196–198]. For this reason, particular emphasis was placed here on minimizing the helium losses in the other product streams. Another particular feature is that the CO_2 is not removed in spite of its relatively high content of 0.9 % in the crude gas. Figure 26 (see next page) shows the process layout.

After removing aromatic hydrocarbons and water in the adsorber (a), CO_2-free top product and a CO_2-rich bottom product is obtained by rectification of a partial stream of the natural gas. The bottom product and the untreated natural gas stream condensed in the reboiler (d) are fed into the lowest section of the medium-pressure column (e). After condensation in the reboiler (d) and in the heat exchanger (l), the CO_2-free top product from column (c) is fed into a higher section of column (e) to extract the CO_2 from the vapor rising from the lower section. In this way all the CO_2 accumulates in the bottom product of column (e) which, due to the presence of C_{2+}

Figure 26. Plant for the extraction of pure helium from Groningen natural gas (Alfortville, France)

hydrocarbons concentrated here, has sufficient dissolving capacity for CO_2 to carry it out of the system without causing any problems.

All the helium introduced by the natural gas flows with the nitrogen to the top of column (e) and is enriched in condenser (f) during the nitrogen liquefaction. Part of the helium is dissolved in the liquid trickling down and is lost with the liquid fractions which are fed from column (e) to the final nitrogen/methane separation stage in the low-pressure column (g). In order to prevent this and to reduce helium losses to a minimum the liquids drawn off are stripped in the reboiler (h) or the column (i). The helium driven off during this procedure is returned to the column (e). In this way, practically all the helium can be extracted at the top of condenser (f) at a concentration of ca. 10 %. In the two following heat exchangers (j) and (k), the helium concentrators, the helium is cooled by evaporating liquids (crude methane and nitrogen) and is enriched to 86 to 90 %.

For further concentration, the crude helium is first compressed by the diaphragm compressor (o) to 200 bar and then cooled until close to the melting point of nitrogen. The refrigeration is provided by liquid nitrogen, which vaporizes in heat exchanger (p) under atmospheric pressure and in heat exchanger (q) under vacuum. The condensate produced is separated in vessel (s) and returned together with the condensates from the concentrators (j) and (k) to the medium-pressure column (e) for recovery of dissolved helium. The helium, which now only contains 0.5 % N_2, is transferred to the final purification stage through the nitrogen-cooled molecular sieve adsorber (t). It leaves this with less than 5 vol ppm impurities. In compressor (u) it is finally compressed to the storage pressure of 350 bar.

During normal operation the system requires no external energy. The fractionation work and refrigeration requirements are covered simply by lowering the pressure of the natural gas. Nevertheless, 72 % of the combustible components can be produced as a medium-pressure fraction at 25 bar.

4.3. Isolation of Argon from Ammonia Purge Gases

In the production of ammonia synthesis gas from natural gas, water vapor, and air in the steam reforming process, the noble gas constituents of the air and those of the natural gas pass into the synthesis gas. Enrichment of those gases together with residual methane, mainly from CO methanization, takes place in the synthesis cycle. In order not to exceed a given inert gas level a portion of the synthesis gas is continuously purged from the cycle and, under normal circumstances, is used as a fuel gas (→ Ammonia, Chap. 4.5.3.5.).

The composition of this purge gas varies according to process type and catalyst age. The average purge gas composition, determined by statistical evaluation of purge gas analyses from about 50 projects, is as follows:

H_2	63.02 mol %
N_2	21.01 mol %
Ar	4.89 mol %
CH_4	11.08 mol %

Trace amounts of NH_3 and H_2O may also be present.

The argon content varies from plant to plant and can range from 3 to 6 mol %. The concentration of the helium depends on the helium content of the natural gas converted in the steam reformer. However, even when processing Groningen natural gas (Netherlands) with only 0.04 – 0.05 % helium appreciable concentrations are obtained in the residual gas, i.e., ca. 0.11 mol %. It can reach values of up to 1 mol %. The other noble gases are of lesser importance.

Hydrogen-depleted purge gas, i.e., the off-gas stream of hydrogen recovery units, which is produced either by membrane separation systems or cryogenically, contains 6 – 12 mol % argon with admixtures of hydrogen, nitrogen, and methane.

Suitable cryoprocesses [199–201] are available for production of noble gases from synthesis purge gas. Initially, extensive separation of nitrogen, argon, and methane is carried out by partial condensation. Purge argon is then recovered from the condensate in a two-stage condensation process. If helium is to be recovered it can be concentrated by liquefaction of the hydrogen in the hydrogen-rich gas phase, followed by purification. The heavier noble gases, krypton and xenon, pass into the methane fraction.

A modern industrial plant for producing high-purity argon, synthesis gas for re-use in ammonia synthesis, as well as liquid nitrogen as by-product was built by Linde for Rashtriya Chem. & Fertilizer Ltd. in Trombay, India in 1993. The process is shown schematically in Figure 27 (see next page).

The purge gas at pressures of up to 70 bar is first introduced into the adsorber (a) where traces of water and ammonia are removed. It is then transferred to the heat exchangers (b_1) and (b_2) for cooling. The gas is then fed into separators (c_1) and (c_2) where separation of liquefied nitrogen, argon, and methane from gaseous hydrogen takes place, and dissolved hydrogen flashes off. The liquid bottom product is fed into the fractionating column (d_1) where methane (bottom) is separated from the nitrogen fraction (top).

A methane-free nitrogen – argon mixture (liquid) is withdrawn from the middle of this column and fed as reflux into the Ar purification column (d_2), where nitrogen is separated from argon. The bottom product is argon of product purity and is transferred to a vacuum-insulated storage tank.

Both columns (d_1) and (d_2) are operated within an N_2 cycle in which cold is produced by expanding high- or medium-pressure nitrogen.

The CH_4 bottom stream from (d_1), compressed by liquid pump (g), is evaporated against feed gas and normally led to battery limits as fuel gas. The higher boiling noble gases krypton and xenon are contained in this stream and, in principle, can be isolated. The process described (operating data are given in Table 20) is the result of continuous improvements in cryogenic argon purge gas recovery, namely the omission of one of the three cryogenic columns normally used and a reduction of the required N_2 cycle pressure from 150 bar to 45 bar at the most. There are three main factors influencing the economy of such a process.

1) N_2/Ar ratio: this affects the cost of argon recovery; the lower the argon concentration the higher the cost of separation.
2) Purge gas pressure: the purge gas pressure also plays an important role in process energy consumption. The higher the pressure,

T, K	283	311	311	83	91
p, bar	27.5	25.5	5.4	9.8	1.4

Utilities consumption: electric power 796 kW, cooling water ($\Delta T = 10$ K) 70 m^3/h.

the lower the cost of separation. This is due to a high Joule – Thomson effect, which in turn relieves the expansion turbine and permits a purge gas dew point that allows almost complete evaporation of the purge gas condensate prior to delivery to the methane separation column, thus reducing the reboiler heat load. The effect of pressure on the system has been deemed so important that the designs are adapted to ensure purge-gas delivery at up to 70 bar.

3) Precooling: an ammonia plant normally provides liquid ammonia at ambient pressure (240 K), which can be used to lower the front-

end entry temperature from cooling water level (305 K) to ca. 249 K. This provides a remarkable level of relief to the expansion turbine cycle.

The so-called hybrid argon recovery process (HARP, Airco, BOC) is a process for argon recovery which has been developed as an alternative to all-cryogenic processes. It is designed to handle hydrogen-depleted ammonia purge gases and make effective use of a combination of pressure swing adsorption (PSA) and cryogenic technology. The main objective of the PSA unit is bulk separation of hydrogen and nitrogen and removal of methane down to a fractional ppm level. A downstream cryogenic section separates and purifies the argon. A schematic representation of the HARP PSA unit is shown in Figure 28. This process has been undergoing extensive laboratory testing [202].

Figure 28. Schematic of the HARP PSA separation

Ammonia synthesis gas that has been produced from heavy oils by partial oxidation is normally purified in a liquid nitrogen wash to such an extent that extraction of a purge gas stream from the synthesis loop becomes unnecessary. The argon carried in with the oxygen in the gas production process is found in the wash liquid; it can be separated from the wash liquid by rectification in a similar manner to the way it is separated from the condensate of a synthesis purge gas. However, the separation is more complicated because of the presence of carbon monoxide with a vapor pressure close to that of argon [203].

Nowadays it is only in exceptional cases that helium is produced from the H_2–N_2 fraction of ammonia purge gas separators or from the hydrogen fraction of plants for hydrogen enrichment from ammonia purge gas. See [204] for these processes.

The quantities of the heavier noble gases, krypton and xenon, in the methane fraction of a purge gas separator are small. This normally contains krypton and xenon in a volumetric ratio of 1: 0.07 with a total content relative to methane (in the case of synthesis gas production by steam reforming) of 30 – 50 vol ppm, depending on the mode of operation of the plant and the age of the catalyst. In a relatively simple process the krypton and xenon can be enriched by rectification and drawn off as a 50 % concentrate. In a subsequent secondary purification process the methane is burnt with the addition of pure oxygen, the combustion product is removed, and the raw krypton – xenon obtained is processed to give pure krypton and xenon [205]. A plant of this type was supplied by Linde in 1988 to Chem-Co, Wratza, Bulgaria. It is intended to produce 34 m^3 xenon and 420 m^3 krypton per year.

5. Liquefaction of Helium

Unlike the other noble gases, helium remains in a gaseous state during the production process. However, helium is increasingly required as a liquid coolant for cooling at very low temperatures. It is also often transported and stored in liquid form.

5.1. Processes for Liquefaction of Helium (see also → Cryogenic Technology)

In the majority of cases helium is liquefied by isenthalpic throttling in a valve (Joule – Thomson valve, JT valve); the proportion of liquid is determined largely by the pressure and

temperature before the throttle valve. The temperature and pressure range in which the temperature drop of the gas needed to produce liquid at each throttling stage takes place in order to liquefy helium by the Linde process is limited by the inversion curve (Fig. 29). The maximum values are 43 K and 38.5 bar; if helium is cooled to a state within this curve then liquefaction is possible. Temperatures below 20 K and pressures of less than 20 bar are usually used for industrial operation.

Figure 29. Joule – Thomson inversion curve

Processes for helium liquefaction can be divided into two categories:

1) Recuperative processes; i.e., the helium is cooled and heated in heat exchangers (recuperators)
2) Regenerative processes; i.e., the helium is cooled and heated in heat accumulators with high thermal capacities and transmission surfaces (regenerators)

Typical representatives of the two categories are described below. The thermodynamic properties for the process calculations can be found in [206].

5.1.1. Recuperative Processes

Compressed helium gas is cooled in heat exchangers to the required precooling temperature. A partial stream is liquefied by throttling at the cold end of the plant. In liquefaction plants the liquid is collected in a tank. The fraction which remains gaseous is heated in countercurrent to the high-pressure gas and transferred to the suction side of the compressor.

Linde Process. Liquefaction of helium by the Linde process is a multi-stage process (cascade).

Liquid hydrogen is suitable for precooling compressed helium to approximately 20 K. If the hydrogen cascade stage also operates on the Linde principle then it also requires precooling as the hydrogen inversion curve is far below the ambient temperature. This precooling is achieved with the aid of liquid nitrogen. The basic layout is shown in Figure 30. The main disadvantage of such a liquefying apparatus is the number of refrigerating cycles required with separately-supplied refrigerants. When hydrogen is used as a refrigerant its combustibility also has to be taken into account, which requires safety precautions.

Figure 30. Cascade arrangement for helium liquefaction
a) Compressors; b) Joule – Thomson valves; c) Heat exchangers

Claude Process (→ Cryogenic Technology, Chap. 3.5.). The number of refrigerants is reduced and the use of hydrogen avoided in the Claude cycle in which helium acts as refrigerant.

In the system designed by KAPITZA and MEISSNER (Fig. 31) helium gas is cooled to a temperature below 20 K while performing work in an expander, so that the precooling of compressed helium required for the Linde process is achieved by countercurrent heat transfer. The first precooling stage at about 80 K with liquid nitrogen is retained as this is generally readily available and causes no problems in relation to plant safety.

Figure 31. Claude cycle for helium liquefaction (Kapitza – Meissner)
a) Compressor; b) Joule – Thomson valve; c) Heat exchangers; d) Expander

Collins Cycle (→ Cryogenic Technology, Chap. 3.7.). An improvement in the energy aspect of helium liquefaction is achieved by incorporating another expander in the closed circuitin the temperature region between 80 and 20 K (Fig. 32). This process was first used by COLLINS and is therefore named after him.

Nowadays the majority of helium liquefaction and refrigeration plants in the lower and medium capacity range use this process. With only one stage the specific energy consumption is 4.8 kWh/L liquid He, a value which is about 22 times as large as the theoretical expenditure (lossless process operation) of about 0.22 kWh/L liquid He under the specified conditions. Introduction of a second precooling stage reduces the expenditure of energy by more than 50 % to 2.3 kWh/L. Additional precooling stages are chiefly of interest for plants with high refrigerating capacities and correspondingly high energy costs. The energy consumption with three stages is 1.8 kWh/L, and with four stages, 1.6 kWh/L.

Figure 32. Collins cycle for helium liquefaction
a) Compressor; b) Joule – Thomson valve; c) Heat exchangers; d) Expanders

5.1.2. Regenerative Processes

The characteristic mode of operation of regenerative processes is explained with the aid of Figure 33. The displacer (a) divides the cylinder into a low-temperature operating chamber (b) and a high-temperature operating chamber (c). The displacer (a) can be moved freely within the cylinder. The two operating chambers are connected with each other via the regenerator (d) – a heat accumulator of high thermal capacity and transfer surface area. During downward movement of the displacer the gas flows at high temperature via the regenerator into the operating chamber (b) and is cooled; as a system with

constant volume is involved, the pressure in the system decreases. If the displacer is moved upwards then cold gas flows to (c) via (d); it is heated and the system pressure increases.

Figure 33. Principle of the regenerative process
a) Displacer; b) Low temperature operating chamber; c) High temperature operating chamber; d) Regenerator

If the displacer is driven by a crank shaft the two volumes and the pressure change periodically with the angle of rotation. However, this change would take place in opposing phases so the resulting refrigerating capacity would be zero. Some work must therefore be applied in the form of pressure variations which have a suitable phase displacement in relation to the changes of the plunger position. This can be carried out in the following possible ways:

1) In the Stirling process (Philips design) a compression piston is located in the hot chamber and has a phase displacement of $-90°$ in relation to the plunger (→ Cryogenic Technology, Chap. 4.4.).
2) In the Gifford – McMahon process pressure changes are generated by changing the gas content of the system for which purpose the system is connected alternately to the high and low pressure sides of a compressor (→ Cryogenic Technology, Chap. 4.7.).
3) In the Vuilleumier process (→ Cryogenic Technology, Chap. 4.5.) two displacer systems are linked. The hot piston (thermal compressor) is housed in a heated cylinder, and the cold piston forms the actual refrigerator. In contrast to the Stirling process the hot (compression) piston here has a phase displacement of $+90°$ relative to the cold (expansion) piston.

These processes have been shown to be industrially feasible for helium liquefaction. However, in most cases they are used for precooling compressed helium gas to the temperature required for liquefaction.

5.2. Gas Purification for Helium Liquefiers

While it is being cooled to liquefaction temperature the helium must be free from all impurities which cause operational problems by freezing out. With the exception of oil most of these impurities are picked up while the liquid helium is being used and must be removed in various purification stages.

The oil which passes into the helium during the compression process is removed in several stages. A typical arrangement is shown in Figure 34. Coarse separation of the oil from the helium takes place in the gravity separator (a) (cyclone separator, demister). Fairly large droplets are retained in the subsequent separator (b) so that gas containing approximately 50 ppm enters the very fine filter combination (c). Separation takes place here typically to less than 0.5 ppm. A residual oil content of less than 10^{-2} ppm is finally achieved in the following active carbon adsorber (d).

Figure 34. Typical design of an oil separation system
a) Gravity separator; b) Separator; c) Very fine filter; d) Active carbon adsorber

Water and carbon dioxide are normally removed at room temperature by alternating drying stations. While one string is in operation

the second string is regenerated by, for example, heating and flushing. This allows the liquefaction to take place on a continuous basis. Silica gels and molecular sieves are suitable for the adsorption of water and carbon dioxide.

At high concentrations (> 1 %) nitrogen and oxygen are first removed by condensation at approximately 65 K. In individual cases this is followed by adsorption at room temperature. The fine purification is then carried out either adsorptively with silica gel at approximately liquid nitrogen temperature (ca. 80 K) or by freezing out in specially designed countercurrent equipment. Adsorbers are normally designed with two strings to achieve continuous operation of the plant, while freezing-out equipment is usually designed with only a single string. This means that during the operational period of the heat exchanger more gas has to be purified than is actually liquefied in order to be able to maintain plant operation during the regeneration period. Both processes provide gas purities of less than 1 ppm.

Neon and hydrogen are normally only present in traces and are removed adsorptively at ca. 30 K. Activated carbon is a suitable absorbent for this purpose. In most cases, a single adsorber has a sufficiently long service life.

5.3. Examples of Helium Cryo Plants

With helium cryo plants it is necessary to differentiate in principle between two modes of operation–the liquefaction operation in which liquid helium is taken from the cryo plant, and the refrigerator operation in which a load is built into the circuit and is cooled by evaporating helium, the saturated vapor being returned to the cryo plant. Many plants are designed for the two modes of operation, either singly or in combination.

5.3.1. Liquefier Using the Claude Process

Cryo plants using the Claude process have the widest range of applications. The capacity range starts at a few watts of refrigerating capacity or liters of liquefying capacity and extends far into the kilowatt range. In practice, only plants using the Claude process are used above ca. 150 W refrigerating capacity.

An example of a small cryo plant is shown in Figure 35 [207]. It was developed specifically to provide liquid helium for nuclear spin tomographs. This requires a superconducting magnet operating at ca. 4.4 K which is surrounded with a helium-cooled radiation shield to reduce the incidence of external heat.

Figure 35. Schematic of a small helium cryo plant
a) Compressor; b) Control valves; c) Heat exchangers; d) Expansion turbines; e) Buffer vessel; f) JT valve; g) Transfer line; h) Radiation shield; i) Current leads j) Magnet with liquid helium bath

The plant operates in a mixed cooling and liquefaction mode. In steady state operation there is an input of 2.9 W to the 4.4 K helium bath; to this is added 1.8 W heat loss of the transfer line from the cryo plant to the magnet. The incidence of heat on the radiation shield is about 60 W. The current leads require 0.012 g/s liquid helium for cooling. The above figures give a 4.4 K equivalent cryo capacity of 14 W. For a drive capacity

of approximately 20 kW this means a specific energy consumption of about 1400 W per watt.

A single-stage oil-injection screw compressor (a) compresses approximately 7 g/s helium from 1.05 bar to 7.4 bar. The high-pressure gas is cooled in countercurrent flow to low-pressure gas in the aluminum plate heat exchangers (c). After the first heat exchanger, ca. 75 % of the high-pressure gas is transferred to the two expansion turbines (d), connected in series. After the last heat exchanger the remaining high-pressure flow is expanded in valve (f) to ca. 1.2 bar, whereby ca. 15 % of the gas stream is liquefied and supplied to the magnet via the transfer line. Two partial streams are taken from the liquid:

1) 0.12 g/s for cooling the radiation shield (h). This stream is returned to the first heat exchanger of the cryo plant at ca. 100 K.
2) 0.012 g/s for cooling the currents lead (i). This part is fed to the suction side of the cycle compressor at ambient temperature.

The remaining liquid is vaporized by the heat input from the magnet. The resulting vapor, together with the helium that remained gaseous in the expansion stage, is warmed in the heat exchanger and fed to the suction side of the cycle compressor.

The plant operates in a closed circuit; it therefore does not require any continuously operating gas purifying equipment with the exception of the oil-retaining system. All components are designed for a maintenance-free operating period of one year.

Figure 36 shows a schematic of a large-scale helium cryo plant used to cool a 6.4 km long ring of superconducting magnets, part of the HERA project for high energy research at DESY, Hamburg [208]. This plant is also used in a mixed cooling and liquefaction operation; 6500 W at 4.3 K are needed to compensate for the heat input into the magnets (g). The heat input to the vaporizing helium in the transfer lines is 275 W. To this is added 20 kW between 40 K and 80 K for cooling the magnet and transfer line radiation shields (e) and 20.5 g/s liquid helium for cooling the current leads (f) of the magnets. This gives a 4.3 K equivalent cryo capacity of approximately 10 kW or a 3000 L/h liquefier. The electrical power consumption of the compressors is ca. 2.9 MW, resulting in a specific energy consumption of approximately 280 W per Watt.

Figure 36. Flow diagram of a large-scale helium cryo plant a) Compressor; b) Heat exchanger; c) Expansion turbines; d) JT valve; e) Radiation shield; f) Current leads g) Magnet

This specific power consumption, which is very low for helium cryo plants, is achieved by several precooling circuits with a total of 7 turbines. The in-series-connected turbines (c_1)–(c_3) cover the temperature range 300 K to ca. 60 K. The turbines (c_4) and (c_5) operate in parallel to (c_1)–(c_3), but are also connected in series with one another, as a second precooling stage with ca. 20 K as the lowest temperature.

The two precooling stages are supplied with high-pressure helium at ca. 18 bar and 16 bar respectively; the outlet pressure from the turbines (c_3) and (c_4) is ca. 2.5 bar. The turbine return gas therefore requires its own passages in the heat exchangers. On the other hand the cryo capacity of the plant can be adapted very simply to the actual requirements by varying the inlet and outlet pressures of the turbines while keeping the pressure ratio constant.

At least 50 % of the total mass flow of approximately 870 g/s is supplied to the cold section of the plant. Unlike conventional designs, two parallel turbines (c_6) and (c_7) are used here before the throttling stage. This configuration permits the use of very small temperature differences between high- and low-pressure streams in the five cold heat exchangers, minimizing the exchange losses between the two streams.

The gas liquefaction takes place at the throttle valve (d) after the last heat exchanger. Because the turbines are positioned upstream the throttling does not take place from compressor final pressure but from ca. 4 bar.

The quantity required for cooling the current leads is drawn off from the resulting liquid and, after heating to ambient temperature, is transferred to the suction side of the compressor. The remaining liquid is vaporized by the heat load and is heated, together with the helium which remained in the gaseous state during the throttling stage, at approximately atmospheric pressure in parallel to the turbine flow.

The helium circuit is compressed in two stages in four machines. The 1 bar stream is compressed with two parallel compressors (a_1), (a_2) and the turbine return gas stream is compressed with one compressor (a_3), all to the same intermediate pressure. From this state the total mass flow is compressed in a second stage (a_4) to the process end pressure.

An external helium purifier can be added if required. It retains air components and operates at ca. 80 K. Continuous operation is achieved with two interchangeable adsorbers filled with silica gel. Liquid nitrogen is used as the refrigerant.

5.3.2. Liquefier Using the Stirling Process

Gas cryo machines using the Stirling process have often been used for the precooling stages in helium liquefaction plants. In more recent developments the Stirling principle is being used increasingly for very small helium cryo plants down to liquid nitrogen temperatures. Figure 37 shows a laboratory scale helium liquefaction plant [209]. The liquefaction capacity is 0.34 g/s (10 L/h) and the specific energy consumption is 2.8 kWh/L helium. This value, which is very good for the size of plant under consideration, is the result of four-stage precooling in the two two-stage gas cryo machines.

Figure 37. Helium liquefier using Stirling machines
a) Compressor; b) Adsorbers; c) Heat exchangers; d) Gas cryo machines; e) Ejector; f) Joule – Thomson valve; g) Helium tank; h) Condensate separator

Compressor (a) compresses ca. 2.5 g/s helium from 2.5 bar to 20 bar. This is a two-stage machine with the pistons sealed by roller diaphragms, which ensures oil-free transport. The high-pressure gas is precooled to ca. 15 K in the heat exchangers (c) by the gas cryo machines (d). After heat exchanger (c_5) it is throttled to 2.5 bar in the ejector (e). The gas flow is then divided: after (c_6) the smaller part is expanded in (f) to 1.1 bar and transferred to the tank (g) in a partially liquefied state. The vapor fraction of the throttled gas after (c_6) is recompressed to 2.5 bar in (e). The larger part of the flow which is subdivided after the ejector is fed to the suction side of the compressor after heating in the heat exchangers.

As a result of extensive segregation of the refrigeration circuit from the gas to be liquefied the gas cleaning system can be confined predominantly to the latter. The gas is dried in adsorber (b_1) and carbon dioxide is retained in adsorber (b_2). Liquid air is separated in the condensate separator (h); the remaining air impurities are retained in (b_3) and (b_4), while neon and hydrogen are removed in (b_5). Only adsorber (b_6) is used for purifying the gas compressed by the compressor.

5.3.3. Helium Cryo Plant Using the Gifford – McMahon (GM) Process

The GM process is used predominantly for small cryo capacities. Although liquid helium temperatures can be achieved with a GM machine, an additional separate Joule – Thomson (JT) circuit should be used for reasons of energy and operational reliability (Fig. 38) [210].

At 4.3 K the maximum cryo capacity of the plant shown is 3.5 W; the drive capacity is 6.4 kW resulting in a specific energy consumption of ca. 1800 W per Watt. The GM machine (d) used for precooling the helium supplies 35 W at 80 K in the first stage and 10 W at 20 K in the second stage. To produce this cryo capacity, 3.9 g/s He is compressed by a reciprocating compressor (a_1) to 23 bar. The compressor has oil injection and is provided with a downstream oil separator system. The two-stage oil-injection reciprocating compressor (a_2) for the JT circuit-compresses 0.36 g/s He from 1 bar to 18 bar. A multistage downstream oil separating system is also used here. Because of the strict separation of the GM and JT circuits the two systems can be operated at different pressures (better efficiency). Impurities in the JT circuit have no effect on the GM machine and vice versa (higher operational reliability).

5.4. Process Developments

In addition to the applications of the classical methods for cryo generation already described there has also been investigation and development work into many other principles. Until now these have practically all been used for very small capacities and very low temperatures. Very often the application is in the forefront of the sphere of space cryotechnology. Some examples taken from the great number of possible methods will be described below.

Adsorption coolers are being developed for producing small capacities in the range 150 K to 0.3 K. This method utilizes heat as the driving energy and requires no moving mechanical parts. Figure 39 [211] shows a schematic of a typical design. The refrigerator consists of several compressors, heat exchangers, precoolers, and a JT valve. The compressors are pressure vessels with adsorbents and they are provided with heating and cooling devices. The functional principle on which this process is based relies on the fact that certain porous materials and sintered metals have a high, temperature-dependent storage capacity for specific gases. This fact is utilized for absorbing, compressing, and expelling

Figure 39. Typical design of an adsorption cooler
a) Compressors; b) On-off valves; c) Heat exchangers; d) Precoolers; e) Consumer; f) JT valve

the gas. A continuous gas flow can be generated in this way with alternate heating and cooling of the adsorbent (compressor).

By heating the compressor (a_1) the gas is compressed and discharged via the corresponding valve (b). The gas is cooled in the heat exchangers (c) and precoolers (d); the isenthalpic throttling takes place in the JT valve (f). After absorbing heat from the consumer (e) the gas returns via the heat exchangers (c) to the cooled compressor (a_2) where it is adsorbed (sucked in).

Magnetic refrigerators (→ Cryogenic Technology, Chap. 4.8.) were originally developed to generate temperatures in the microkelvin range, but are now also finding applications at higher temperatures. The functional principal is based on the magnetocaloric effect. In magnetic substances the atoms behave like very small bar magnets. Due to their thermal movements the atoms have completely irregular alignments. When an external magnetic field is applied at very low temperature the magnetic dipoles become aligned. If the magnetic field is then switched off again the dipoles attempt to return to the disordered equilibrium state. The energy required for this is withdrawn from the lattice vibrations; the lattice and magnetic moments achieve thermal equilibrium again. This procedure cools the magnetic material.

Figure 40 shows the principle design of a magnetic refrigerator for recondensation of helium [212] as an example of the application of this principle. If a high intensity magnetic field is generated by the pulsed magnets (e) the temperature of the magnetic material (a) increases. To reduce the temperature again heat is removed via the cooling circuit (b). After the heat has been removed the magnet is switched off; there is a further drop in temperature of the magnetic material. Heat can now be taken from the helium bath (c) via the transfer tube (d), during which helium vaporized from the bath is recondensed.

Figure 40. Example of a magnetic refrigerator, principle design
a) Magnetic material; b) Cooling circuit; c) Helium bath; d) Transfer tube; e) Magnets

^{3}He – ^{4}He Dilution Refrigerators (→ Cryogenic Technology, Chap. 4.9.). All the plants described so far use helium-4. However, helium-3 has much to recommend it for achieving very low temperatures down to the mK region because of its significantly higher vapor pressure at the same temperature. At very low temperatures ^{3}He is not soluble in all proportions in ^{4}He; there is an extensive dilution zone. Below 0.1 K the light phase consists of almost 100 % ^{3}He, which, however, accounts for only

approximately 6 % of the heavy phase. During its transition from the light into the heavy phase with the associated dilution the ^{3}He is cooled. This permits the supply of heat from a load at constant temperature.

Figure 41 shows the principle design of a dilution refrigerator [213]. Precooled helium at a pressure in the millibar region is throttled in capillary (a_1). The helium is cooled further in the distillation vessel (b) and the heat exchanger (c) between which is positioned a second throttling capillary (a_2).

Figure 41. Basic design of a segregation cryo station
a) Throttles (capillaries); b) Distillation vessel; c) Heat exchanger; d) Mixing chamber; e) Aqueous phase; f) Concentrated phase

The helium is now introduced into the mixing chamber (d) where it passes from the light to the heavy phase. After absorbing heat from a load the helium flows from the mixing chamber, through the heat exchanger (c), and into the distillation vessel (b) because of the difference in concentration. There it is vaporized and fed to the compressor.

Although the concentration of ^{3}He in the liquid in the distillation vessel is very low, the vapor consists of virtually 100 % ^{3}He. The helium recirculating in the closed loop is therefore almost pure ^{3}He. The ^{4}He in the system is virtually stationary in the distillation vessel, heat exchanger, and mixing chamber.

6. Quality Specifications and Analysis

New technical advances are leading to increasingly stringent requirements for the purity of noble gases. For example, even traces of impurities in pure gases could adversely affect the operation of gas lasers, and exceeding a given isotopic ratio would limit their use in the nuclear industry. Most gas suppliers use the so-called point notation, where, for example, He 5.8 means a minimum purity of 99.9998 % and Ar 6.0 denotes argon of minimum purity 99.9999 %. Contents of impurities are usually given in vol ppm or ppb [214]; mg/m^3 and mg/kg are also used. Typical purity grades of commercially available noble gases are between 4.0 and 6.0.

The following impurities are found in noble gases:

1) Oxygen and nitrogen, which enter during transfer of noble gases with gas transfer systems that are not gas-tight
2) Hydrocarbons, from contaminated pipes or compressors
3) Water, desorbed from the walls of insufficiently pretreated gas cylinders
4) Carbon dioxide from various sources
5) Perfluorinated hydrocarbons, which are enriched during production of the crude fraction in air separation plants
6) Hydrogen, which can result from the process for the purification of noble gases.

Empirical methods for the analysis of noble gases, such as the lamp test formerly used in the lighting industry [215], have since been superseded by physical or physicochemical analytical methods. Methods such as measurement of the density, vapor pressure, and refractive index have declined in importance, partly because the quantities of gas required are too large [216]. The following are the most widely used methods:

1) Gas chromatography, with various detectors. Low-boiling hydrocarbons can be determined in all noble gases with a detection limit of 0.1 vol ppm by using a flame ionization detector. The so-called total hydrocarbon analyzer also gives the total hydrocarbon content (C_nH_m) with a detection limit of 0.1 vol ppm. The helium ionization detec-

tor can be used to detect traces of H_2, O_2, N_2, CH_4, CO, and other noble gases. Similar sensitivity is exhibited by the argon detector [217]. This is a discharge detector in which the excitation is produced by high-frequency a.c. current. It has proved very sensitive for the detection of impurities in argon.

2) Dispersive and nondispersive (NDIR) infrared spectroscopy allows the quantitative and qualitative determination of heteroatomic molecules having characteristic absorptions. The limit of detection for hydrocarbons is < 1 vol ppm. Similar sensitivity is attainable for CO_2 due to the intense absorption at 2349 cm^{-1} [218, 219]. Due to ease of use, NDIR instruments have become well established in the analysis of gases [220].
3) Moisture in noble gases is determined by using electrolytic or capacitive hygrometers. In laboratories, water content is sometimes determined by measurement of the dew point in a Peltier-cooled apparatus. The moisture content is usually expressed as a dew point. Tables for conversion to vol ppm, mg/L, and other units are available in the literature.
4) Oxygen is determined electrochemically in a further development of the oxygen-specific cell patented by Hersch [221, 222].

7. Uses

7.1. Welding

Argon and helium are used in the welding, cutting, and spraying of metals. Depending on the welding process, the noble gases are used pure, as a mixture, or in combination with oxygen, hydrogen, or carbon dioxide [224]. Typical applications are as follows:

1) Ar, Ar – He mixtures, and He for tungsten inert gas (TIG) and metal inert gas (MIG) welding of aluminum and its alloys [225]
2) High-purity Ar for TIG welding of gas-sensitive metals such as titanium, tantalum, and tungsten
3) Mixtures of Ar with oxygen (up to 8 vol %) and/or carbon dioxide (up to 3 vol %) for MIG welding of high-alloy steels [226]. Part of the argon can be replaced by helium
4) Argon – hydrogen mixtures for TIG welding of austenic steels
5) Argon-based mixtures with high contents of oxygen (up to 12 %) and carbon dioxide (usually 18 %, sometimes more) for MIG welding of construction steels. Part of the argon can be replaced by helium
6) Argon as a plasma gas for plasma welding and argon-hydrogen mixtures (> 5 % H_2) as protective gases for plasma welding

Protective gases for welding are standardized in DIN 32 526. A corresponding EN standard is being prepared. The purity of the gases is very important, usually exceeding 99.99 % with a dew point < -50 °C.

7.2. Illumination

Neon, argon, krypton, and xenon are used as filler gases for lamps, sometimes as constituents of gas mixtures. High-purity gases are required for these applications.

Neon is used as the filler gas for high-voltage tubular lamps. This application is, however, of minor importance. These crimson lamps are used for advertising signs. In addition, neon, with small additions of other gases, is used in low-voltage neon-glow lamps and in starters for fluorescent tubes.

Argon, as a mixture with nitrogen, is the most widely used filler gas for conventional light bulbs.

Krypton is used as the filler gas for high-quality light bulbs. Compared to argon or nitrogen, krypton reduces the rate of evaporation of the tungsten filament and, due to its low thermal conductivity, lowers its rate of cooling. Krypton-filled lamps have higher light efficiencies and color temperatures than lamps filled with other gases. Halogen lamps are filled with krypton that contains controlled amounts of iodine- or bromine-containing compounds. The use of krypton for lamps has increased with the introduction of energy saving lamps.

Xenon is used in gas-discharge lamps. The xenon discharge has an almost continuous spectrum, resembling daylight. Therefore,

Xenon is highly suitable for lamps where the quality of the color is of particular importance. Furthermore, high light efficiencies can be achieved. Xenon lamps are used for projectors, for illumination of film and television recordings, in floodlights, as flashlights, and as navigation lights for runways.

7.3. Other uses

Argon is used in metallurgy as a protective gas for annealing at temperatures at which nitrogen would react with the metal, as a scavenger gas for the degassing of molten metals, and in the AOD process for the production of chromium steels.

High-purity argon is used in the production of silicon for the semiconductor industry. In the production of chips, it is used as a protective gas and as a carrier gas for dopants. It is also used as a protective and carrier gas in spark and ICP spectrometry and gas chromatography.

Helium is used on account of its special properties when use of another gas is impossible or only partially feasible.

European consumption of helium in 1997 broke down as follows:

Low-temperature technology	36 %
Welding, cutting	14 %
Optical fibers	8 %
Breathing mixtures, diving	6 %
Analysis	14 %
Leak detection	9 %
Balloons	7 %
Other uses	6 %

Liquid helium is used in cryogenic technology as a refrigerant, for example, for superconducting magnets:

1) For magnetic resonance imaging tomography in medical diagnosis,
2) In NMR spectrometers,
3) In particle accelerators,
4) In magnetic separators, and
5) For research in solid-state and high-energy physics.

Other uses include cryopumps for ultrahigh vacuum, superconducting sensors (SQUID's), superconducting memories and circuit elements in computers, and low noise amplifiers. Interesting potential uses are the cooling of superconducting power station generators, electromotors for ships, and nuclear fusion reactors.

Gaseous helium is used in rocketry for conveying liquid fuel and for inerting rocket motors.

In diving, helium is used instead of nitrogen to avoid problems of decompression. In medicine it is used to improve the ease of breathing of asthma sufferers, and helium-containing gas mixtures are used to investigate the functioning of the lungs.

Helium is used as a carrier gas in gas chromatography, as a filler gas for thermometers, and in counter tubes for the measurement of high-energy radiation. Helium is of importance in leak detection in plant construction and vacuum technology. It can be used to detect even the smallest leaks. This application exploits the high rate of diffusion of helium and the high sensitivity of helium mass spectrometers.

Helium is used for filling balloons and airships. Its high buoyancy and nonflammability make it especially suitable for this purpose.

Helium is used as a coolant in high-temperature nuclear reactors. Helium-4 is the only element that gives no radioactive products upon high-energy irradiation. The high thermal conductivity of helium is important in this application.

Helium is essential to many high-technology processes, an example being the production of optical glass fibers, in which it serves as a coolant and as a carrier gas for the chlorine used for the removal of hydroxyl groups. Finally, helium is the major component in the gas mixture used in the CO_2 laser.

Neon is used in the excimer laser, in which ittakes part in the energy transfer process. It is also used in the He – Ne laser. Liquid neon is now commercially available and is finding application as an economical cryogenic refrigerant. It has over 40 times more refrigerating capacity per unit volume than liquid helium and more than three times that of liquid hydrogen.

Xenon shows promise for use in medicine and medical applications. Xenon-enhanced computerized tomography and xenon magnetic resonance imaging (MRI) are used for investigating blood flow in the brain and in the lungs. Xenon can also be used as anesthetic in place

of the more familiar nitrous oxide. The physiological impact is enhanced because of the good solubility of xenon in fat tissue [223].

The use of xenon as a fuel for ion drives for space vehicles could allow the replacement of chemical fuels by nuclear or solar energy in space flight. For this purpose xenon is ionized by electrical energy and accelerated to high velocity by electrodes. Ion drives are also suitable for stabilization of missiles. Commercial use can be expected in the near future. In high-energy physics, xenon is used in radiation counter tubes.

8. Storage and Transportation

Gaseous noble gases are transported in steel cylinders comparable to those used for other industrial gases. In Germany this is usually a 50 L steel cylinder with 20 MPa overpressure. Also available are 10 L cylinders, and 1 L and 2 L cylinders for the expensive noble gases neon, krypton, and xenon. Small amounts of noble gases are delivered in glass flasks (1 or 2 L). Disposable pressure cans with a volume up to 1 L and an overpressure of 1.2 MPa are also available. Large quantities of gases are transported in 600 L cylinder bundles or road tankers with 13 – 20 m^3 volume and 20 MPa overpressure. For high-purity requirements, special withdrawal fittings are required that have minimal leak rates and a small dead volume and can be heated and evacuated.

Large amounts of argon are transported in liquid form. Stationary and transport tanks for liquid argon are powder vacuum insulated and resemble tanks for liquid oxygen and nitrogen in design.

Containers for the transport of liquid helium are made of high-alloy stainless steels. The inner container in which the liquid helium is located is connected to the outer container only by a neck. Heat absorption from the surroundings is minimized by superinsulation, high vacuum, and thermal radiation shielding. The superinsulation is a multilayer coating of insulating and reflecting foils around the inner container. The radiation shields between the inner and outer containers carry heat to the tube, which is cooled by evaporating helium. The structure of a liquid helium dewar is shown in Figure 42.

Figure 42. Helium dewar, cooled by evaporating helium
a) Tube; b) Superinsulation; c) Outer jacket; d) Radiation shielding; e) Container for liquid helium; f) Cooling tube system; g) Adsorbent; h) Support

Independent of the filling level, boil-off losses amount to 1 % per day relative to the full container. This means that in a 1000 L container the heat absorption from the surroundings is only 0.3 W/d.

Stationary helium tanks are built with volumes up to 100 m^3. Small amounts of liquid helium are transported in containers with 30 – 500 L volume. For long distance transport, road tankers with 3.7 or 41 3 volume are used.

Liquid helium is usually transferred by pressurization with gaseous helium. The liquid helium passes through a vacuum-insulated siphon into the container to be filled. Helium suppliers collect the resulting evaporated helium, which is then either reliquefied or filled as gaseous helium into cylinders. Such a system is, however, not economically viable for most helium users.

9. Economic Aspects

Helium. In the 1990s helium demand worldwide steadily increased at a growth rate of approximately 7 – 10 % per annum. In 1993 helium

Table 21. World helium production for 99.995 purity (Grade A) or better, in 10^6 m^3 [227]

Country or region	1990	1992	1994	1995	1996	1997	1998
United States	84.9	94.4	100.4	96.1	94.7	107	108
U.S. exports	24.7	30.7	25.0	27.7	22.8	29.5	29.7
Algeria			12	16	16	16	16
Poland	4	4	2	1.9	1.4	1.4	1.4
Former Soviet Union			4.0	4.0	4.2	4.2	4.2
Other countries							
World total	89	98.4	118.4	118	116.3	128.6	129.6

production amounted to some 100×10^6 m^3, 95 % of which was supplied by U.S. private and Bureau of Mines plants. About 30 % of U.S. helium production is exported, and in 1997, for instance, ca. 55 % of U.S. exports were shipped to Asia, mostly Japan, and 20 % to Europe. From 1994 on Poland, Russia and Algeria gradually accounted for 20 % of annual world production. Table 21 shows world helium production statistics. As per December 1997 the world helium annual production plant capacity including plants on standby was 160 million cubic meters. One-third of the helium is delivered in liquid form as a refrigerant.

The price for helium depends on quantity ordered, liquid or gaseous, type and size of cylinders, and regional factors. The following are approximate prices at given conditions: United States: Bulk price f.o.b. helium plant in 1997 \$ 1.98 per m^3 (STP) gaseous, \$ 2.5 per m^3 (STP) as liquid. Europe (1999): € 4 to 10 per liter (in transport cans), He, compressed in steel cylinders from € 30/m^3 (STP) (purity 4.6) to € 80/m^3 (STP) at purity 6.0 (99.9999 %).

Argon. Argon is the only noble gas used industrially in bulk quantities. Most of the argon is produced in air separation plants with an argon rectification column; only a minor amount comes from ammonia tail gas separation units. More than 80 % is used for metallurgy and metal processing. In 1998 ca. 2×10^9 m^3 of argon was used worldwide. Total U.S. argon production amounted to 3500 t/d equal to 0.7×10^9 m^3 per year. One-third of the argon is used in the United States, one-third in Europe and one-third in the rest of the world. Liquid argon shipped by truck costs approximately € 0.8 – 1.5 per m^3 (gaseous), whereas cylinder fillings in laboratory quality costs appr. € 15 per m^3 (STP).

Neon, Krypton and Xenon. These gases are produced exclusively in air separation plants. Increasing amounts are being used for lighting, lasers, and medical application. Given high growth rates and new applications, the availability of these gases, particularly the extremely rare gas xenon, could become a problem in the future: 100 m^3 of pure xenon corresponds to the annual production of an air separation plant producing 50 000 m^3/h of oxygen. World production of xenon in 1998 was estimated to be 5000 – 7000 m^3 per annum.

The prices of these rare gases depend on quantity ordered, the purity required, type and size of cylinders, and regional factors. The following are approximate prices for the purchase of small quantities in Europe (1999):

Neon: € 0.20/L
Krypton: € 1/L
Xenon: € 10/L

1. Introduction

Traditional linear optics are based on optical phenomena arising from interaction between light and materials whose optical properties (e.g., refractive index) are independent of the applied light intensity (→ Optical Materials). In nonlinear optics the optical properties of the material are a function of the electrical field strength of high-intensity light (i.e., a laser) or an externally applied electrical field.

Expansion of research activity in nonlinear optics (NLO) has been largely stimulated by the rapid development of laser technology and increasing importance of optical technology in telecommunication and information processing. Advances in NLO science span broadranging frontiers, covering new phenomena (e.g., frequency doubling in optical fibers), optical materials (e.g., NLO polymers), and optical devices (e.g., soliton lasers).

The demonstration of NLO properties required the availability of a high-power, coherent light source (i.e., the laser, → Lasers). Modern NLO owes its beginning to Franken [1] who demonstrated second harmonic generation (i.e., frequency doubling) of a ruby-laser beam with a quartz crystal. In the 1960s much of the fundamental theoretical framework was established by Bloembergen [2]. With the advent of optical fiber telecommunications in the late 1970s (→ Fiber Optics), the industrial importance of NLO was fully appreciated. This resulted in intensive research in NLO and its applications during the 1980s. Information is now often carried on a laser beam in communication processes, data storage, retrieval, sensing, or display. Increasing effort is being made to obtain even greater data manipulation by use of ultrafast optoelectronic interactions and by harnessing the inherent parallelism of optical signals.

In parallel with the development of the understanding of NLO phenomena is the increasing variety and sophistication in NLO materials. Early materials were largely based on inorganic dielectric crystals, and atomic and molecular gases. The possibility that organic materials could provide more efficient NLO properties was first realized in 1969 [3]. In organic materials, NLO properties are related to molecular electronic transitions, and electron density variations are easily obtained; fast-response, large-magnitude NLO properties can therefore be obtained.

The first reported work on NLO polymers was by Meredith [4], in which *N,N′*-dimethylaminonitrostilbene dyes were dissolved in a side- chain liquid crystal polymer and an asymmetric material structure was created by applying an external electrical field. This concept was further extended by Hoechst Celanese to polymeric materials: the NLO chromophores are attached as side chains to methacrylic chains thereby increasing the chromophore concentration in the materials. Furthermore, the electrically poled structure is stabilized and exhibits the long relaxation time of glassy polymer materials.

In polymeric third-order materials, a molecular structure is required that allows a long electron delocalization length. Investigations in the 1980s were focused on polydiacetylenes, polyacetylenes, and other modifications of electrically conducting polymers. Since third-order NLO effects are relatively small in magnitude and the materials tend to absorb too strongly at most wavelengths suitable for optical applications, progress has lagged behind that in the secondorder materials area.

Since the early 1980s the range of NLO materials has been expanded by the production of new artificial semiconductor materials, e.g., multiple quantum wells, quantum wires, quantum dots, and superlattices. Multiple quantum wells are fabricated by growing alternate layers of two different semiconductors, typically GaAs and AlGaAs [5]. This produces an alternating succession of potential hills and valleys for electrons and holes; the carriers are confined in the potential wells, thereby exhibiting quasi-two-dimensional behavior that leads to large optical nonlinearities.

The physics of NLO are reviewed in Chapter 2. Surveys of recent developments in second-order and third-order materials are given in Chapters 3 and 4. Potential applications of the materials and material property requirements are discussed in Chapter 5.

2. Nonlinear Optical Phenomena

Electromagnetic radiation can be regarded as an oscillating electrical field. When a light beam (a form of electromagnetic radiation) is incident on, for example, an inorganic crystal, the ions in the crystal lattice are polarized and oscillate with the radiation. This polarization of the ions in turn induces a small electric field which alters the direction and diminishes the magnitude of the field of light (→ Optical Materials). In linear optics the polarization is proportional to the incident radiation and is responsible for phenomena such as refraction and reflection of light. A laser, however, may have a peak field strength

of 10^7 V/m which is comparable to the forces binding the ions together. Thus polarization induced by lasers can induce highly nonlinear oscillations, i.e., the polarization of the ions is not proportional to the incident radiation. This gives rise to nonlinear phenomena such as optical mixing and harmonic generation.

2.1. Macroscopic Nonlinear Optics

2.1.1. Maxwell Equations and Constitutive Relations

Maxwell equations describe classical electromagnetic phenomena and contain terms to account for nonlinearity. It is through the electric polarization $\boldsymbol{P}$ that nonlinearity enters the Maxwell equations, according to the expansion in the dipole approximation

$$\boldsymbol{P} = \chi^{(1)}\boldsymbol{E} + \chi^{(2)}\boldsymbol{E}\boldsymbol{E} + \chi^{(3)}\boldsymbol{E}\boldsymbol{E}\boldsymbol{E} + \ldots \tag{1}$$

where $\boldsymbol{E}$ is the electric field, $\chi^{(1)}$ the linear optical susceptibility, $\chi^{(2)}$ the second-order NLO susceptibility, etc. The Maxwell wave equation is then written as

$$\nabla \times (\nabla \times \boldsymbol{E}) = -\mu \frac{\partial^2}{\partial t^2}\left[\chi^{(1)}\boldsymbol{E} + \chi^{(2)}\boldsymbol{E}\boldsymbol{E} + \chi^{(3)}\boldsymbol{E}\boldsymbol{E}\boldsymbol{E} + \ldots\right] \tag{2}$$

where

$$\nabla = \left(i\frac{\partial}{\partial x} + j\frac{\partial}{\partial y} + k\frac{\partial}{\partial z}\right)$$

∇ is the spatial derivative of the three cordinates *x, y,* and *z*, $\times$ refers to the cross product of the vectors, and μ is the magnetic permeability. The essence of NLO is embodied in Equation (2). When ultrashort (subpicosecond) light pulses are considered, Equation (1) must be modified since $\boldsymbol{P}$ at time t is a result of electric fields present at times t' ($t' < t$). Advances in ultrashort pulse lasers have now allowed observation of a host of subpicosecond phenomena based on this principle.

2.1.2. Second-Order Nonlinear Optical Phenomena

In the majority of optical materials (i.e., linear optical materials) the second-order term $\chi^{(2)}$ is zero. This is due to fundamental material symmetry considerations; macroscopic second-order NLO phenomena do not occur in centrosymmetric media such as gases, liquids, and most solids. Only materials lacking a center of inversion can exhibit bulk second-order [$\chi^{(2)}$] phenomena; examples are lithium niobate, potassium dihydrogen phosphate (KDP), gallium arsenide, gallium phosphide, lithium tantalate, barium titanate, quartz, copper(I) chloride, 2-methyl-4-nitroaniline, and electrically poled NLO polymers (Chap. 3); these materials also exhibit piezo- and pyroelectric effects. Since interfaces between media are noncentrosymmetric, $\chi^{(2)}$ phenomena are also induced at interfaces and $\chi^{(2)}$ effects have been used to study interfacial phenomena [6]; $\chi^{(2)}$ effects are also found in chiral media [7].

Low-Frequency $\chi^{(2)}$ Phenomena. Several $\chi^{(2)}$ phenomena (e.g., electro-optics, optical rectifications, and magneto-optics) involve the application or production of a low-frequency electromagnetic field. Extensive research in second-order NLO has been directed toward electro-optic materials, waveguides, and devices since materials exhibiting large electro-optic effects under low applied fields are already available. The effects are rapid ($\tau < 1$ ns), making high-speed switching possible. Only low-power light sources (e.g., semiconductor laser diodes) are required and in the early years of NLO a viable waveguide technology was available for lithium niobate, a perovskite crystal electro-optic material.

The *electro-optic effect* is a change in the refractive index n of a medium induced by an applied electric field according to

$$\Delta\left(\frac{1}{n^2}\right)_i = \sum_{j=1}^{3} r_{ij}\boldsymbol{E}_{\mathrm{m}j} \tag{3}$$

where $\boldsymbol{E}_{\mathrm{m}_j}$ is the j-th component of the modulating field $\boldsymbol{E}_{\mathrm{m}}$, r_{ij} the electro-optic tensor, and the index i of the two-dimensional tensor is an integer between 1 and 6.

The electro-optic effect is described by a second-order polarization $\boldsymbol{P}^{(2)}$ resulting from the interaction of an applied low-frequency electrical field $\boldsymbol{E}(\omega_m)$ and an optical field $\boldsymbol{E}(\omega_o)$ such that

$$\boldsymbol{P}^{(2)}(\omega_o \pm \omega_m) = \chi^{(2)}(-(\omega_o \pm \omega_m); \omega_o, \pm \omega_m)\, \boldsymbol{E}(\omega_o)\, \boldsymbol{E}(\pm \omega_m) \quad (4)$$

where $(\omega_o \pm \omega_m)$ is the frequency of light leaving the material, ω_o is the frequency of light entering the material, and ω_m the frequency of the applied electrical signal. The total electric field $\boldsymbol{E}(\boldsymbol{r}, t)$ is given as a continuous function of the position vector $\boldsymbol{r}$ and time t by

$$\boldsymbol{E}(\boldsymbol{r},t) = \boldsymbol{E}_0 + \frac{1}{2}\sum_{i=1}^{N}\left[\boldsymbol{E}(\omega_i)\, e^{-\omega_i t} + \text{c.c.}\right] \quad (5)$$

and similarly for $\boldsymbol{P}^{(2)}(\boldsymbol{r}, t)$; the term c.c. denotes complex conjugate. Equation (4) describes the frequency dependence of $\chi^{(2)}$. The induced polarization frequency is the negative of that on the right-hand side of the equation. Equation (4) shows that the electro-optic effect corresponds to the creation of an induced polarization and thereby an electric field through Equation (2), at sideband frequencies $\omega_o - \omega_m$ and $\omega_o + \omega_m$. Usually ω_m is approximated to zero; this is not, however, reliable at high switching speeds (gigahertz) or when the source bandwidth is less than the modulation frequency ω_m.

In *optical rectification* (an inverse electro-optic effect) two optical waves interact to create a low-frequency electrical field. The advent of subpicosecond pulses of large bandwidth has allowed the use of optical rectification to create terahertz pulses of "low-frequency" radiation in a controlled manner in electro-optic crystals such as lithium tantalate [8].

Magnetic fields and optical fields interact in some media to produce *magneto-optic effects*; optical properties can be changed by applying a magnetic field. Typical magneto-optic media are rare-earth doped glasses and crystals. These materials are being applied to optical isolation, optical data storage, and in modulating devices. Magneto-optics are used for optical isolation because the direction in which an optical beam's polarization is rotated is independent of its direction of propagation.

Interesting effects have been observed in multiple quantum well (MQW) structures (Fig. 1) that involve interplay of absorbed light, generated currents, and applied electric fields [9]. An example is observed in self electro-optic effect devices (SEEDs) [10]. These devices work on the principle that changes in the optical absorption of a MQW can be induced by changes in the electric field perpendicular to the quantum well stacks. When used in conjunction with conventional semiconductor structures such as *p-i-n* diodes, this effect can be used to make optical switches; small switching energies (4 pJ) have been demonstrated [11].

Figure 1. Multiple quantum well (MQW) structure made from alternating layers of GaAs and AlGaAs

All-Optical $\chi^{(2)}$ Phenomena. The first observed second-order all-optical effect was second harmonic generation (SHG) of ruby-laser light in crystalline quartz, i.e., some of the incident light at 694 nm was converted to light with half this wavelength (347 nm) [1]. The induced polarization at the second harmonic frequence is given by

$$\boldsymbol{P}^{(2)}(2\omega) = \chi^{(2)}(-2\omega; \omega, \omega)\, \boldsymbol{E}(\omega)\, \boldsymbol{E}(\omega) \quad (6)$$

The input fields are at ω and ω and have a positive sign on the right-hand side of the semicolon. The output field is at frequency 2ω on the left-hand side of the semicolon; by convention output fields have a negative sign.

The intensity at the second harmonic frequency $I_{2\omega}$ depends on the intensity at the fundamental frequency I_ω according to (no pump depletion)

$$I_{2\omega} = \frac{8\omega^2 d_{\text{eff}}^2 L^2}{n_{2\omega} n_\omega^2} \left(\frac{\mu_0}{\varepsilon_0}\right)^{3/2} (I_\omega)^2 \operatorname{sinc}^2\left(\frac{\Delta k L}{2}\right) \quad (7)$$

where d_{eff} is the effective nonlinearity, L the length of the medium, n_ω and $n_{2\omega}$ the refractive indices at the fundamental and the second harmonic frequencies, μ_0 the vacuum magnetic permeability, ε_0 the vacuum electric permittivity, $\Delta k = 2\omega\,(n_{2\omega} - n_\omega)/c$, and sinc $\xi = \sin \xi/\xi$. (ξ is a dummy variable). The result illustrates two features of second-order NLO: firstly the SHG intensity is quadratic in d_{eff}, L, and I_ω, and secondly it depends on the function $\operatorname{sinc}^2(\Delta kL/2)$.

When phase-matching conditions are satisfied, $\Delta k = 0$ and $\operatorname{sinc}^2(0) = 1$ but when $\Delta k \neq 0$, $\operatorname{sinc}^2(\Delta kL/2)$ reaches its largest value at one coherence length defined by $l_{\text{coh}} = \lambda/4\,(n_{2\omega} - n_\omega)$. The coherence length is the distance over which the beams of fundamental frequency (ω) and the second harmonic (2ω) travel coherently. If phase matching is perfect, the coherence length becomes infinite and a large second-harmonic intensity can be obtained. In most materials l_{coh} is ca. 20 – 30 µm and the amount of SHG is small without phase matching. Phase matching can be accomplished by using crystal birefringence or anomalous dispersion in bulk materials or through modal dispersion in waveguides. Quasi-phase matching in which the optical medium incorporates a nonlinearly varying periodicity equal to l_{coh} has been demonstrated in bulk crystals and waveguides [12, 13].

Second harmonic generation is a special case of the general second-order interaction between optical fields at frequencies ω_1, ω_2, and ω_3, where $\omega_3 = \omega_1 + \omega_2$. For SHG $\omega_1 = \omega_2 = \omega$ and $\omega_3 = 2\omega$. In *sum-frequency generation* $\boldsymbol{E}(\omega_2)$ is converted to $\boldsymbol{E}(\omega_3)$ through interaction with an intense pump field $\boldsymbol{E}(\omega_1)$. Sum-frequency generation is useful for converting IR signals that are difficult to detect into visible signals for which detectors with high quantum efficiency (i.e., high sensitivity) are available. Sum frequency generation has been used to generate 450 – 500 nm radiation with a diode laser and a diode pumped Nd : YAG (yttrium aluminum garnet) laser as sources in a $KTiOPO_4$ (KTP) crystal [14]. *Difference frequency mixing* involves generating $\boldsymbol{E}(\omega_2 = \omega_3 - \omega_1)$ from $\boldsymbol{E}(\omega_1)$ and $\boldsymbol{E}(\omega_3)$ through suitable NLO interactions in a medium. Difference frequency mixing can be used to generate tunable IR radiation at wavelengths which are difficult to reach with existing laser sources. If a nonlinear medium is placed in an optical cavity between two appropriate mirrors, injection of an intense pump beam $\boldsymbol{E}(\omega_3)$ into the cavity can result in the spontaneous creation of photons at different frequencies (ω_1, ω_2) with conservation of energy. Those photons fed back into the nonlinear medium can stimulate more emission at their respective frequencies. This device is known as an *optical parametric oscillator* (OPO) and is a source of tunable radiation over large wavelength ranges (hundreds or even thousands of nanometers) [15]. Difference frequency mixing can also be applied to amplify a weak beam (parametric amplification) and for generating sub-Gaussian-noise laser pulses (squeezed states) [16]. The latter are laser pulses which have uncertainties in their amplitudes or phases that are less than the standard limit set by the Heisenberg uncertainty principle.

2.1.3. Third-Order Nonlinear Optical Phenomena

Third-order [$\chi^{(3)}$] NLO phenomena are symmetry allowed in all media. However, they are usually observed at laser powers that are several orders of magnitude higher than those required for $\chi^{(2)}$ effects. This is because the ratio of successive terms in Equation (1) is given by $|\boldsymbol{P}^{(n+1)}/\boldsymbol{P}^{(n)}| \approx |\boldsymbol{E}/\boldsymbol{E}_{\text{atomic}}|$, where $\boldsymbol{E}$ is the applied electric field and $\boldsymbol{E}_{\text{atomic}}$ is the average atomic electric field (10^4 V/µm) on an electron. An optical field of equivalent strength would correspond to intensities of 5×10^{14} W/cm^2. If 100 kW/cm^2 is assumed to be a reasonable intensity for NLO interactions $|\boldsymbol{E}| \approx 0.4$ V/µm, so that $|\boldsymbol{E}/\boldsymbol{E}_{\text{atomic}}| \approx 10^{-5}$. Large $\chi^{(3)}$ effects can, however, be observed when there is resonance between the sum of the applied field frequencies and a material energy level.

Macroscopic $\chi^{(3)}$ phenomena can result from a variety of microscopic manifestations, one of which is nonlinear distortion of electron clouds (the primary mechanism for $\chi^{(2)}$ effects). Two other important mechanisms leading to $\chi^{(3)}$ responses are based on orientational and thermal effects. Orientational effects are due to nuclear

motion in response to applied optical or low-frequency electrical fields resulting in a field-dependent anisotropy of the refractive index. Thermal effects involve absorption of light by the system and dissipation of some of the absorbed energy as heat. The resulting temperature rise produces local changes in density which are manifested as refractive index changes.

Intensity-Dependent Refractive Index Phenomena. These are NLO effects in which the refractive index n of a medium is changed by an intense optical or electrical field, the change in n is proportional to the square of the applied field

$$n = n_0 + \frac{1}{2} n_2 c \left(\varepsilon\varepsilon_0\right)^{1/2} \left|\boldsymbol{E}_{\mathrm{pump}}\right|^2 \tag{8}$$

where c is the speed of light, $|\boldsymbol{E}_{\mathrm{pump}}|$ the pump field amplitude, n_0 the linear index of refraction, n_2 the nonlinear index of refraction, ε the dielectric constant of the medium, and ε_0 the vacuum permittivity. For an electric field with two main Fourier components, $\boldsymbol{E}(\omega_0)$ (the pump field) and $\boldsymbol{E}(\omega)$ (the probe field) where $|\boldsymbol{E}(\omega_0)| >> |\boldsymbol{E}(\omega)|$, the polarization at ω is

$$\boldsymbol{P}^{(3)}(\omega) = \chi^{(3)}(-\omega;\omega,\omega_0,-\omega_0)$$

$$\boldsymbol{E}(\omega_0)\,\boldsymbol{E}(-\omega_0)\,\boldsymbol{E}(\omega)$$

where ω_0 is the frequency of the electrical field perturbing the material and ω the frequency of the beam used to test the effect of the pump field on the properties of the material. When $\omega_0 = 0$, the *d.c. Kerr effect* results, in which birefringence is induced by an electric field. To detect this the sample is placed between crossed polarizers and the increase in transmission is measured on application of a large d.c. field [17] (see also Section 4.2). The amount of probe light transmitted is quadratic in the intensity of the d.c. field (Eq. 8).

When ω_0 is an optical frequency, optically induced birefringence (i.e., the *optical Kerr effect*, OKE) occurs. This was first observed in 1964 in several molecular liquids (carbon disulfide, benzene) with a Q-switched ruby laser [18]. Studies using 100 fs pulses show a variety of new molecular motion phenomena in molecular liquids [19]. In solid media the OKE is due solely to electron cloud distortion and is the basis for many proposed ultrafast all-optical devices.

Self action effects are $\chi^{(3)}$ phenomena that require only one laser beam and do not generate any new frequencies. Examples are self focusing and self phase modulation. *Self focusing* (Fig. 2) occurs because all laser beams have a lateral extension with the peak intensity at the center. In $\chi^{(3)}$ materials the refractive index may increase with laser intensity (Eq. 8). The laser beam creates a refractive index profile for itself that mimics its own intensity profile. When $n_2 > 0$, the beam is focused and its intensity increases until either dielectric breakdown occurs or a stable self-guided beam is formed in which positive self focusing balances diffraction. Self focusing

Figure 2. Self focusing in a material with an intensity-dependent refractive index

has implications for areas as diverse as optical computing and laser fusion. Self-guided waves (spatial solitons) have been observed in glass [20] and thermal defocusing effects have been seen in semiconductors and liquids.

Self phase modulation denotes that the phase of a beam depends on its intensity and has important implications for ultrafast optical signal processing and pulse propagation. It is observed in optical media with an intensity-dependent refractive index. The uncertainty principle states that subpicosecond optical pulses should have very large frequency bandwidths. Most materials have a positive refractive index dispersion causing a short pulse to spread out (the red parts of the pulse travel faster than the blue parts). This group velocity dispersion (GVD) can be made negative (i.e., the blue parts of the pulse travel faster than the red parts) in wavelength regions where the material or waveguide exhibits anomalous dispersion, while self phase modulation works in the same direction as positive GVD. With an appropriate temporal intensity profile these effects can cancel and temporal solitons result, i.e., pulses that do not spread out. Solitons have been demonstrated in optical fibers [21] and the same principle has been used to shape and compress pulses [22] (see also Section 5.4).

Frequency Generation Phenomena. Many $\chi^{(3)}$ phenomena result in the creation of new frequencies and, as in the $\chi^{(2)}$ case, phase matching and material transparency are difficult to achieve. The simplest frequency-generating $\chi^{(3)}$ effect is *third harmonic generation* (THG), in which part of a laser beam is converted into a beam whose wavelength is one third of the original beam; a field with a frequency three times the fundamental frequency is generated. As in SHG, $\boldsymbol{E}(3\omega)$ builds up over a coherence length $l_{\mathrm{coh}} = \lambda/6\,(n_{3\omega} - n_{\omega})$, which is of the order of $10-20\,\mu\mathrm{m}$. Phase matching is not possible unless the material is highly birefringent or anomalous dispersion effects are used. THG is a useful characterization technique for $\chi^{(3)}$ materials (see Section 4.2).

Since $\chi^{(2)}$ is a third-order tensor it behaves very much like a vector (a first-order tensor). In a symmetric material these odd-order tensors cannot exist because they are cancelled. If a high d.c. field is applied to a solution of polar molecules molecular alignment occurs breaking the center of symmetry and allowing SHG to occur; this is known as d.c.-induced second harmonic generation (DCSHG) or electric-fieldinduced second harmonic. Since three input fields are involved (the applied d.c. field and the input optical beam which is counted twice), this is a $\chi^{(3)}$ phenomenon with frequency dependence $\chi^{(3)}(-2\omega;\omega,\omega,0)$. This technique is used for measuring molecular hyperpolarizabilities β (corresponding to $\chi^{(2)}$) and γ (corresponding to $\chi^{(3)}$) of molecules in solution [23].

Stimulated Raman scattering refers to the generation of a coherent light beam of a new frequency when an incoming laser beam interacts with a material that is undergoing a vibrational transition. It is another frequency-generating NLO effect that is automatically phase-matched and can be used to achieve $10-20\,\%$ conversion of light to Raman-shifted wavelengths. With optimal focusing and control over polarization, discrete tunability with good conversion efficiencies can be achieved over many hundreds of nanometers in the visible and near infrared. The best media for stimulated Raman scattering are molecular gases and liquids.

Four-wave mixing occurs when three incident beams with wave vectors $\boldsymbol{k}_1$, $\boldsymbol{k}_2$, and $\boldsymbol{k}_3$ interact to create a fourth beam at $\boldsymbol{k}_4$. Conservation of momentum gives

$$\boldsymbol{k}_4 = \boldsymbol{k}_1 \pm \boldsymbol{k}_2 \pm \boldsymbol{k}_3 \tag{9}$$

where $\pm$ refers to the electric field. When $\omega_4 = \omega_1 = \omega_2 = \omega_3 = \omega$, degenerate four-wave mixing results and is automatically phase-matched. Degenerate four-wave mixing can occur through nonresonant electronic $\chi^{(3)}$ effects, light-induced concentration gratings, and thermal effects (thermal gratings). It can be used to create phase- conjugate mirrors that "undo" image distortions and reflect the incident beams back on themselves (Section 5.3). Spectacular effects are observed in crystals such as barium titanate and lithium niobate where the microscopic origin of the effect (photorefraction) is the motion of photo-induced electrical changes coupled to an electro-optic effect [24].

Resonant and Nonresonant $\chi^{(3)}$ Effects. The treatment of resonant NLO effects includes the analysis of populations of electronic excited

states. Resonance occurs when some algebraic combination of applied frequencies is equal to an eigenfrequency (inherent frequency) of the system and large enhancement of $\chi^{(2)}$ or $\chi^{(3)}$ can result. With a single applied field of frequency ω_0, one-photon enhancement occurs when ω_0 is close to Ω (a material eigenfrequency), and two-photon enhancement can occur when ω_0 is close to $\Omega/2$. Energy conservation alone does not guarantee large enhancement since, in the case of multiphoton processes, symmetries of the excited states and the ground state of the system are involved. Saturable absorption is an important NLO effect in which large populations of excited state energy levels result in a dramatic increase in the transparency of a system when enough light is present near the resonance frequency. Disadvantages of resonant NLO effects for device applications include high absorption and long recovery times.

2.2. Microscopic Nonlinear Optics

Macroscopic NLO phenomena are based on various microscopic mechanisms.

2.2.1. Constitutive Relations and Local Fields

The constitutive relation between the microscopic dipole moment $\boldsymbol{p}$ and the microscopic electric field $\boldsymbol{e}$ is

$$\boldsymbol{p} = \mu + \alpha \boldsymbol{e} + \beta \boldsymbol{e}\boldsymbol{e} + \gamma \boldsymbol{e}\boldsymbol{e}\boldsymbol{e} + \ldots \tag{10}$$

where μ is the microscopic permanent dipole moment, α the linear polarizability tensor, β the first hyperpolarizability tensor, and γ the second hyperpolarizability tensor. Equation (10) can only be used when a well-defined source of microscopic hyperpolarizability exists. The same symmetry rules as for the macroscopic properties then result, so that only noncentrosymmetric microscopic entities may have nonvanishing β (and nonvanishing μ) while α and γ are nonvanishing for all entities.

The microscopic NLO susceptibilities β and γ are related to the macroscopic NLO susceptibilities $\chi^{(2)}$ and $\chi^{(3)}$ by an averaging procedure. Thermodynamic, orientational, and local field averaging are required along with superposition of a macroscopic number of microscopic units. Orientational averaging is trivial for a gas or a weakly interacting liquid since all orientations may be assumed to be equally probable and the averaging relies solely on geometric factors. For crystals, liquid crystals, and oriented glasses or polymers, the positions and orientations of the microscopic elements must be included in the averaging. It is difficult to perform local field averaging in dense media. The Lorentz–Lorenz local field theory is adequate for gases and weakly interacting liquids and solids. In this theory the relationship between the microscopic field $\boldsymbol{e}$ and the macroscopic field $\boldsymbol{E}$ is $\boldsymbol{e} = (\varepsilon + 2)\boldsymbol{E}/3$, where ε is the dielectric constant of the medium. Connecting the $(n-1)$-order microscopic hyperpolarizability to the nth-order macroscopic NLO susceptibility requires $(n+1)$ local field factors; local field effects can be significant for higher-order NLO phenomena.

2.2.2. General Classical Models

In linear optics many useful results are obtained by modeling the motion of an electron in an atom as a forced simple harmonic oscillator where the forcing field is the applied optical field. The model can be extended to describe NLO effects by including an anharmonic term in the equation of motion:

$$\frac{d^2x}{dt^2} + G\frac{dx}{dt} + \omega_0^2 x + ax^2 = \frac{F}{m} \tag{11}$$

where x is the position of the electron, Γ is a damping term, $a << \omega_0^2/A$ (A is the amplitude of the electron's motion), $\boldsymbol{F}$ is the electric field force ($\boldsymbol{F} = -e\boldsymbol{E}$), e is the electron charge, and m the electron mass. Let $\boldsymbol{E}$ have two primary frequency components

$$\boldsymbol{E} = \left[\frac{1}{2}\boldsymbol{E}(\omega_1)\, e^{-i\omega_1 t} + \text{c.c.}\right] + \left[\frac{1}{2}\boldsymbol{E}(\omega_2)\, e^{-i\omega_2 t} + \text{c.c.}\right] \tag{12}$$

and attempt to solve Equation (11) perturbatively. The zeroth-order solution gives classic Lorentzian oscillators, with two solutions $x^{(1)}(\omega_1)$ and $x^{(1)}(\omega_2)$, corresponding to the two frequencies ω_1 and ω_2. Then

$$\left(x^{(1)}\right)^2 = \left(\frac{a}{2m}\sum_{i=1}^{2}\frac{\boldsymbol{E}(\omega_i)\,e^{-i\omega_i t}}{(\omega_0^2 - iG\omega_i - \omega_i^2)}\right)^2 \quad (13)$$

and the expansion of this quadratic gives terms with frequency dependences $2\omega_1$, $2\omega_2$, $\omega_1+\omega_2$, $\omega_1-\omega_2$, and zero frequency terms. Each of these terms acts as a source for a different frequency component of the motion. Equation (11) can be solved for $x^{(2)}(2\omega_1)$, i.e., microscopic SHG

$$x^{(2)}(2\omega_1) = \frac{\frac{a}{2}(e/m)^2\,\boldsymbol{E}^2(\omega_1)}{(\omega_0^2 - iG\omega_1 - \omega_1^2)\,(\omega_0^2 - 2iG\omega_1 - 4\omega_1^2)} \quad (14)$$

This solution exhibits a quadratic dependence on $\boldsymbol{E}(\omega_1)$, as well as frequency denominators having resonances at $\omega_1 = \omega_0$ and $\omega_1 = \omega_0/2$. As $x^{(2)}$ solutions have more frequency dependence than $x^{(1)}$, higher order terms have even more dispersion. Difficulties in relating NLO measurements on the same material at different light frequencies are due to dispersion factors.

2.2.3. Quantum Mechanical Treatment of Nonlinear Optics

The correct way to describe the interaction of matter with radiation is by using quantum mechanics. The first step in the quantum mechanical treatment is to determine the Hamiltonian of the system, H. Usually $H = H_0 + H'$, where H_0 is the Hamiltonian of the system in the absence of radiation and H' is the interaction between the system and the applied fields, usually taken to be $H' = -e\boldsymbol{r}\cdot\boldsymbol{E}$ for a one-electron system. In the sum-over-states (SOS) approach, the time-independent Schrödinger equation is solved through a self-consistency scheme, such as the Hartree–Fock theory. Time-dependent perturbation theory is then used to compute corrections to the zeroth order wave functions resulting from the presence of H′. The polarization density is calculated as the expectation value of the polarization operator, and the microscopic susceptibilities can be extracted. This procedure gives the following for $\beta_{ijk}(-\omega_3;\omega_1,\omega_2)$:

$$\beta_{ijk}(-\omega_3;\omega_2,\omega_1) = \frac{8\pi^3 e^2}{h^3}P(\omega_1,\omega_2,\omega_i,\omega_j)\left[\sum_{mn}{}' \frac{\langle r_i\rangle_{gm}\langle \bar{r}_j\rangle_{mn}\langle r_k\rangle_{ng}}{(\Omega_{ng}-\omega_j)(\Omega_{mg}-\omega_i-\omega_j)} + \frac{\langle r_j\rangle_{gm}\langle \bar{r}_i\rangle_{mn}\langle r_k\rangle_{ng}}{(\Omega_{mg}^*+\omega_i)(\Omega_{ng}-\omega_j)} + \frac{\langle r_k\rangle_{gm}\langle \bar{r}_j\rangle_{mn}\langle r_i\rangle_{ng}}{(\Omega_{ng}^*+\omega_j)(\Omega_{mg}^*+\omega_i+\omega_j)}\right] \quad (15)$$

where ω_3 is the frequency of the induced polarization wave, ω_1 and ω_2 the applied frequencies, e the electron charge, h Planck's constant, $P(\omega_i, \omega_j, \omega_1, \omega_2)$ a permutation operator, the sum is over all states except the ground state, $\Omega_{ng} = \Omega_n - \Omega_g$ is the frequency difference between states n and g of the system, and the barring operator is defined by $\langle\bar{A}\rangle_{mn} = \langle A\rangle_{mn} - \langle A\rangle_{gg}$. Expressions such as Equation (15) have been used to calculate the microscopic NLO susceptibilities β and γ [25,26].

The above discussion applies only to the motion of electrons, but similar approaches apply for contributions to the microscopic NLO susceptibilities from nuclear motion (vibrational and rotational effects). In general, the macroscopic NLO susceptibilities do not stem directly from their microscopic counterparts; exceptions are SHG, parametric mixing, THG, and nondegenerate four-wave mixing. The macroscopic NLO susceptibility normally depends upon several different microscopic NLO susceptibilities (e.g., DCSHG, $\chi^{(3)}$ depends on μ, β, and γ).

3. Second-Order Nonlinear Optical Materials

3.1. Inorganic Materials

Inorganic Crystals. As discussed in Chapter 2, a material must be noncentrosymmetric for a second-order NLO effect to occur. In addition, it should also be transparent to all frequencies involved in the nonlinear interaction. Quartz satisfies these requirements and is readily available as large, perfect single crystals. Quartz has therefore played an important role in the development of NLO materials. The efficiency of SHG (i.e.,

frequency doubling) in quartz is very small because of the low nonlinearity of the material and the fact that the SHG cannot be phase-matched.

The discovery of phase matching [27] came shortly after the discovery of SHG with the use of ammonium dihydrogen phosphate (ADP) [*7722-76-1*] and potassium dihydrogen phosphate (KDP) [*7778-77-0*] crystals. Unlike quartz these two materials have large birefringences so that an incidence angle of the optical beam can be adjusted to provide phase matching between the fundamental and second harmonic waves. With this new phase-matching technique and the crystals' reasonably high resistance to laser damage, SHG efficiences approaching 10 – 50 % were reported with pulsed lasers. The deuterated form of KDP, designated KD∗P, is standard in commercially available laser systems for frequency doubling from the near infrared into the visible.

The next major advance came with the discovery of lithium niobate [*12031-63-9*], $LiNbO_3$, as an NLO material [28]. Lithium niobate offers several advantages over ADP and KDP. It is nonhygroscopic, hard, can be polished to a good finish, and has a large nonlinear coefficient. In addition, the temperature sensitivity of its birefringence is such that phase matching can be achieved by varying the temperature. Furthermore, soon after the discovery of lithium niobate as an electro-optic material, researchers discovered ways to make controlled waveguides by diffusion of titanium into the lithium niobate when heated at high temperature to increase its refractive index. Lithium niobate is, however, easily damaged when illuminated by a continuous wave laser. This photorefractive effect manifests itself as a track of slightly altered refractive index in the crystal along the path of the laser beam. For many practical purposes this effect is not detrimental but is devastating for efficient phase-matching interactions in which the relative phases of the waves are crucial. Despite this disadvantage, lithium niobate remains a very important NLO material.

New, efficient materials are emerging that show promise for a wide range of optical technologies. β-Barium borate (BBO) [*13701-59-2*], β-BaB_2O_4 [29], contains ionic groups with planar conjugated π-orbitals (as in organic molecules) whose electron clouds are polarized more efficiently by incoming radiation. This results in greater nonlinearity and thus in more efficient SHG. The material is transparent in the UV and exhibits an effective $\chi^{(2)}$ 4 – 6 times that of KDP.

Other materials for frequency-doubling lasers include lithium triborate (LBO) [*12007-41-9*], LiB_3O_5, and L-arginine phosphate (LAP) [*49720-39-0*]. Study of certain ferroelectric materials consisting of octahedral crystals containing oxygen and bonds with large nonlinear polarizabilities (TaO, TiO, etc.) has led to the development of potassium titanyl phosphate (KTP) [*12690-20-9*] [30] which is stable and may replace KD∗P in many applications.

Semiconductors. Semiconductors (e.g., GaAs [*1303-00-0*] and ZnS [*1314-98-3*]) play an important role in electro-optic modulators (devices that switch light partially or totally on or off at a very fast speed) in the IR region; most conventional electro-optic materials (e.g., KDP) are opaque in this region (although $LiNbO_3$ transmits from 0.4 to 5 μm). Apart from the need for a large electro-optic coefficient, the criteria for choosing electro-optic semiconductors include an energy gap larger than the photon energy of the light being modulated. This insures freedom from interband transitions that render the material opaque. Conducting currents from the modulating field result in electrical losses and therefore a good material for electro-optic applications should have high electrical resistivity as well as a low free-carrier absorption (free carriers are the electrons and "holes" in the semiconductor). Optical absorption by free carriers can lead to attenuation of the optical signal and additional heating.

Multiple Quantum Wells. A semiconductor quantum well is a thin heterostructure of a low-band-gap material (e.g., GaAs) sandwiched between two layers of high-band-gap material (e.g., AlGaAs). The thickness of the low-band-gap material is ca. 10 nm or about 30 – 40 atomic layers (Fig. 1). A typical MQW structure might consist of approximately 100 such layers totaling about 1 μm.

Interest in the use of MQW materials in optical modulators has recently increased because the electroabsorptive effect [31] (one of the phenomena responsible for light modulation

in such devices) is ca. 50 times larger than in bulk semiconductors. In addition, the technology of layered semiconductor growth is well established because it has long been used in many optoelectronic devices such as laser diodes (→ Electroluminescent Materials and Devices, Chap. 3.).

3.2. Organic Materials

Origin of Optical Nonlinearity in Organic Materials. Interest in organic materials has steadily grown since the 1980s due to their potentially superior properties over inorganic compounds. In inorganic crystals, optical nonlinearity originates from oscillations of positive and negative ions which have relatively large masses. This restricts both the speed of oscillation and displacement. The origin of nonlinear phenomena in organic materials lies in their conjugated π-electrons; this involves transport of electrons, responses are therefore both fast and large in amplitude.

Organic molecules such as benzene have centrosymmetric structures and therefore do not show second-order NLO properties in the electric-dipole approximation. The necessary acentric structure for a second-order material can be provided in the benzene ring by distorting the π-electron cloud. This can be achieved by replacing some of the hydrogen atoms on the ring with functional groups that act as strong electron donors or acceptors. In 4-nitroaniline, the molecular ground-state dipole moment points nearly axially across the ring from the amino group to the nitro group. Since the amino group is an efficient electron donor and the nitro group an efficient electron acceptor, the excited state is relatively stable and has a strong nonlinear response.

Organic Crystals. A number of organic single crystals that show considerable optical NLO effects have been identified and synthesized. These include urea [*57-13-6*] [32], 2-methyl-4-nitroaniline (MNA) [*99-52-5*] [33], 2-(*N,N*-dimethylamino)-5-nitroacetanilide (DAN) [*5367-36-2*] [34], 3-methyl-4-nitropyridine *N*-oxide (POM) [*1074-98-2*] [35], (2,4-nitrophenyl)-aminopropanoate (MAP) [*10420-63-0*] [36], and *N*-(4-nitrophenyl)-(*S*)-prolinol (NPP) [*88422-19-9*] [37]. Research into organic crystals for second-order applications primarily involves the ability to grow asymmetric crystals of sufficient optical quality and size. Structural tailoring of the molecular units sometimes permits the realization of asymmetry and is an important feature of organic materials.

The disadvantages of many organic crystals, however, are that they lack mechanical strength and are highly suceptible to chemical attack, since the molecular lattice is preserved only by relatively weak Van der Waals forces.

Langmuir – Blodgett Films. Certain organic molecules exhibit amphiphilic behavior because they contain both hydrophilic and hydrophobic regions which can be preferentially ordered as a monomolecular layer at an air–water interface. By compressing the film to nanometer dimensions, and employing a dipping process, this film can be transferred onto a suitable substrate. Multilayered structures (Langmuir – Blodgett films) can be formed over relatively large areas by repeated dipping. An example of an organic molecule used for this technique is the merocyanine dye described in [38].

A high degree of noncentrosymmetric polar order can theoretically be achieved using this method. In practice, however, stable noncentrosymmetry can only be maintained over a few layers. For waveguide applications, ca. 1 μm thick guiding layers are required, corresponding to more than 500 layers. It is therefore unlikely that the Langmuir – Blodgett technique will find applications in the fabrication of NLO waveguides.

3.3. Nonlinear Optical Polymers

Organic Guest – Host Systems. Large areas can be covered with nonlinear optical films by using techniques such as spin coating or dip coating. Thicknesses of up to 20 μm can easily be obtained. The spin solution can be prepared by dissolving a NLO-active guest molecule with an inactive host polymer [e.g., poly(methyl methacrylate)] in a suitable solvent. After spinning, drying, and solvent evaporation a film of the nonlinear molecules remains embedded in the host polymer.

For a material to possess second-order nonlinear effects, it must be noncentrosymmetric. The asymmetry in a spin-coated film can be achieved with electric field poling described below.

Poling of NLO Polymers. Electric field poling involves heating the polymer to a temperature at which it is in a viscous state [39]. A strong electrical field is then applied, and active NLO chromophores align as a result of interaction of their dipole moment with the electric field. This process usually takes place in the vicinity of the polymer glass transition temperature (T_g) and is counteracted by thermal disordering effects. When equilibrium is reached (usually in a few minutes) the polymer is cooled to room temperature before the electric field is removed and the alignment is thus frozen in a metastable state. The electro-optic coefficient r of the resulting poled polymer can be written as

$$r \sim N f \beta \frac{\mu E}{kT} \tag{16}$$

where N is the number density, f the local field correction, β the intrinsic molecular second-order nonlinearity, μ the dipole moment of the NLO chromophore, E the poling field, k the Boltzmann constant, and T the temperature. Therefore, to achieve large macroscopic second-order nonlinear effects the $\mu\beta$ product can be increased or the applied poling field can be maximized, the latter is limited by the dielectric strength of the polymer. Poling efficiencies of 10 – 20 % are typically achieved.

Thermal Stability of Poled Polymers. Long-term stability of the poled polymer is critically important because the poled structure is inherently in a nonequilibrium state. Relaxation in polymers arises from thermal reorientational effects whose rate is governed by the molecular mobility. The mobility is in turn determined by environmental parameters including storage temperature and molecular properties such as the glass transition temperature T_g and the free-volume content. The higher the T_g of the polymer, the more stable is its poled structure [40].

Cross-Linked Polymer Matrix. In some poled NLO polymers the chromophores are covalently bonded in a cross-linked polymer matrix [41]. The NLO chromophore (e.g., 4-nitro-1,2-phenylenediamine [41]) is reacted with an optically passive bifunctional epoxy monomer to form a soluble prepolymer that can be spin coated onto a flat substrate. Since this involves a chemical reaction at elevated temperature (ca. 140 °C), poling must be accomplished before curing is complete. A mild precure produces a gel that can withstand reasonable poling electric fields without breakdown before completion of the chemical reaction.

Main-Chain and Side-Chain Polymers. Polymeric solid solutions have several disadvantages in practical applications. They suffer from low packing densities of the NLO chromophores due to phase separation, opacity, low breakdown fields, and poling stabilities that are below commercial requirements. Polymers now being investigated generally utilize chemical bonding between the "guest" NLO and the inactive "host" material. Polymers have been synthesized in which the NLO chromophores are incorporated in the main polymer chain, so the dipoles all point in the same direction (head-to-tail). This molecular configuration offers a very high chromophore density and a potentially more stable alignment than guest – host systems. However, it is questionable whether effective poling alignment can be achieved in such systems.

Covalent attachment of the active NLO unit to the polymer backbone as a pendant side chain (Fig. 3) [42] not only increases the NLO density but also prevents the phase separation observed in guest – host systems. This is because one end of the moiety is permanently attached to the polymer backbone. Furthermore, the side-chain architecture gives sufficient mobility to respond to electrical poling, while providing enough poling stability for commercial applications.

Extensive research has been carried out on these systems. For example, materials such as 4-nitroaniline, disperse red, and dimethylamino-4-nitrostilbene have all been covalently attached to backbones such as polymethacrylate, poly(methyl methacrylate), polystyrene, polysiloxanes, and polycarbonates. The resulting materials show good SHG (frequency doubling) efficiencies and electro-optic coefficients comparable with or exceeding those of lithium niobate, as well as good poling stability. In one experiment, polymers were made with a predicted

80 % retention of the poling over a period of 5 years at 70 °C [40].

Figure 3. Methyl methacrylate polymer with NLO units attached to the polymer backbone via side chains

3.4. Examples of SHG Materials

The choice of nonlinear material for SHG depends on the application and the performance required. The key requirements in selecting a nonlinear crystal are a large phase-matching transparency range, high conversion efficiency, good optical homogeneity, good environmental stability, and ease of production. Organics generally have very high optical nonlinearities and high damage thresholds, but a transparency cut-off near 450 nm. Potassium titanyl phosphate does not suffer from a transparency cut-off but is very difficult to grow with sufficient optical quality. β-Barium borate and L-arginine phosphate are easier and cheaper to grow, have high transparency and wide phase-matching ranges; the latter has an extremely high optical damage threshold. Concerted efforts in improving crystal growth will make them attractive for high-power applications such as laser fusion, and low-power applications such as integrated optical devices and frequency conversion of miniature diode-pumped lasers. Table 1 shows SHG coefficients of some inorganic and organic materials.

3.5. Examples of Linear Electro-Optical Materials

As described in Section 2.1.2, the electro-optic effect arises from an anisotropic change in the refractive index of the material upon application of a d.c. electric field, quantified by the electro-optic tensor r_{ij}. If a linear polarized beam is incident on such a material, its two resolved orthogonal components will travel at different velocities through the crystal as a result of the induced birefringence. Upon emerging from the crystal a phase difference exists between these two components, the amount of retardation depending on the crystal, the crystal symmetry, dimensions, and the applied voltage. If the crystal is placed between crossed polarizers, the change in phase between the two polarizations causes a change in the transmittance of the beam.

Table 1. Second harmonic generation (SHG) coefficients of some inorganic and organic materials

Material	Wavelength transparency range, nm	d_{eff} [a], pm/V	Figure of merit [b]
Inorganic materials			
Potassium dihydrogen phosphate (KH_2PO_4)	200 – 1500	0.6	0.11
Deuterated potassium phosphate (KD_2PO_4)	200 – 1500	0.4	0.05
Potassium titanyl phosphate ($KTiOPO_4$)	350 – 4000	7.4	9.40
β-Barium borate (β-BaB_2O_4)	190 – 3500	1.6	0.60
L-Arginine phosphate	220 – 1950	1.1	0.30
Organic materials			
2-(*N,N*-dimethylamino)-5-nitroacetanilide	430 – 2000	27	148
N-(4-Nitrophenyl)-(*S*)-prolinol	500 – 2000	102	2000
3-Methyl-4-nitropyridine	414 – 2000	8	13
2-Methyl-4-nitroaniline	400 – 2000	31	170
		$d_{11} = 250$ [c]	

[a] $_{\mathrm{eff}}$ is the effective second-order nonlinear coefficient for a fundamental wavelength of 1.064 µm.
[b] Figure of merit is defined as d^2_{eff}/n^3 in units of $(\mathrm{pm/V})^2$ and is a measure of the second harmonic generation efficiency; n = refractive index.
[c] The d_{11} coefficient of 2-methyl-4-nitroaniline is not phase-matchable in bulk crystals.

Table 2. Linear electro-optic coefficients of some organic and inorganic materials

Material	Symmetry of crystal structure	$n^3 r$ [a]	Mode of operation	Reduced V_π (633 nm) [b], kV
Inorganic materials				
Lithium niobate ($LiNbO_3$)	3m	$1/2\,(n^3{}_e r_{33} - n_0^3 r_{13}) = 112$	transverse	2.94
Deuterated potassium phosphate (KD∗P)	42m	$n_0^3\, r_{63} = 90$	longitudinal	3.50
SBN : 60 [c]	4mm	$1/2\,(n^3{}_e r_{33} - n_0^3 r_{13}) = 1300$	transverse	0.25
β-Barium borate (β-BaB_2O_4)	R3c	$n_0^3\, r_{yyy} = 11.6$	transverse	56.0
Organic materials				
3-Nitroaniline	mm2	$1/2\,(n^3{}_z r_{33} - n^3{}_y r_{23}) = 63$	transverse	5.0
2-Methyl-4-nitroaniline	Cc	$1/2\,(n_1^3\, r_{11} - n_3^3 r_{31}) = 270$	transverse	1.3
DCNP [d]	Cc	$1/2\,(n^3{}_z r_{333}) = 860$	transverse	0.37

[a] n = refractive index; r = linear electro-optic coefficient. [b] The reduced V_π is calculated when the ratio of the thickness to the length of the crystal is normalized to 1. [c] Strontium barium niobate $Sr_{0.6}Ba_{0.4}Nb_2O_6$ [43].
[d] 3-(1,1-Dicyanoethenyl)-1-phenyl-4,5-dihydro-1*H*-pyrazole [44].

The efficiency of an electro-optic device can be defined in terms of the voltage required to induce a phase retardation of π radians and hence a switch from full extinction to full transmission. This is referred to as the half-wave voltage V_π. Such an electro-optic modulator has two modes of operation: the transverse configuration (electric field applied perpendicular to the direction of light propagation), and the longitudinal configuration (electric field applied parallel to the direction of propagation). The half-wave voltage required depends on which configuration and hence which components of r_{ij} are sampled. Table 2 shows the values of electro-optic parameters for some inorganic and organic materials.

3.6. Thin Film Applications

Thin films for integrated optical waveguides have a number of advantages over bulk materials. The small cross section of the waveguide structure can produce very high optical intensities which, when combined over long interaction lengths, can give rise to efficient nonlinear processes even with low-power lasers. Their compatibility with optical communication systems makes this class of devices very useful.

Electro-optic devices are generally fabricated using titanium-diffused $LiNbO_3$. Recent studies include efficient frequency doubling and difference frequency generation in Ti : $LiNbO_3$ and proton exchanged $LiNbO_3$ waveguide structures.

Various methods can be used for depositing organic polymers onto substrates. Spin coating, dipping etc. can result in large area coverage at relatively low temperatures (150 °C). Techniques such as photolithography can then be used to define the waveguide region. Since the resulting films are centrosymmetric, they need to be electrically poled. Results obtained using this poling technique are encouraging, achieving electro-optic coefficients greater than those of $LiNbO_3$. The low dielectric constant of these films compared to $LiNbO_3$ also makes them attractive for high-speed applications. Table 3 shows a comparison of properties of electro-optic materials for thin film applications.

Table 3. Comparison of some properties of electro-optic materials for thin film applications

Material	ε [b]	n	r, pm/V	$n^3 r$, pm/V	Figure of merit [c]
P2ANS/MMA [a]	3.2	1.63	> 40	> 170	> 54
$LiNbO_3$	16.5	2.2	30	328	20
GaAs	6.5	3.4	1.6	60	9

[b] The value given is the effective dielectric constant for coplanar waveguide electrodes on the material's surface.
[c] Figure of merit is defined as $n^3 r/\varepsilon$.

4. Third-Order Nonlinear Optical Materials

A number of second-order NLO materials have been used in commercial products and others show promise. No developed products based on third-order NLO effects exist apart from some liquid crystal display devices based on the d.c. Kerr effect (see Section 2.1.3). Reasons for this include the lack of well-defined systems applications and the high cost of powerful lasers, but the main difficulty is materials development.

4.1. Fundamental Requirements for $\chi^{(3)}$ Materials

The third-order NLO susceptibility, $\chi^{(3)}$ relates the third-order nonlinear polarization $\boldsymbol{P}^{(3)}$ and the applied electric field $\boldsymbol{E}$ through $\boldsymbol{P}^{(3)} = \chi^{(3)} \boldsymbol{E}\boldsymbol{E}\boldsymbol{E}$, or in indicial form (Chap. 2)

$$\boldsymbol{P}_i^{(3)} = \chi_{ijkl}^{(3)} \boldsymbol{E}_j \boldsymbol{E}_k \boldsymbol{E}_l \tag{17}$$

For many device applications an intensity-dependent refractive index is desired, often expressed as the nonlinear refractive index n_2, where

$$n = n_0 + \frac{1}{2} n_2 c \left(\varepsilon\varepsilon_0\right)^{1/2} \langle \boldsymbol{E}\boldsymbol{E} \rangle \tag{18}$$

with n_0 the linear refractive index, ε the dielectric constant of the material, ε_0 the permittivity of free space, c the speed of light, and $\boldsymbol{E}$ the monochromatic applied field. The relationship between n_2 and $\chi^{(3)}{}_{xxxx}$ is given by

$$n_2 = \frac{1}{c} \left(\frac{1}{n_0 \varepsilon_0} \right) \chi_{xxxx}^{(3)} \tag{19}$$

where $\chi^{(3)}{}_{xxxx}$ is the completely diagonal component of $\chi^{(3)}$ with all fields and polarization taken to be in the x-direction.

The other quantity often quoted is the *microscopic third-order NLO susceptibility*, γ. There is some confusion in the literature concerning the definition of γ. In Section 2.2, γ was defined in terms of the microscopic field and represented only electronic NLO processes. It is reasonable to extend this viewpoint so that $\gamma = \gamma_{\mathrm{el}} + \gamma_{\mathrm{lat}}$, where γ_{el} is the electronic contribution of γ and γ_{lat} is that due to lattice motions. However, γ is often defined as the microscopic average of $\chi^{(3)}$ (i.e., $\gamma = \chi^{(3)}/NF$, where N is the number of microscopic elements per unit volume and F a local field factor).

Another crucial requirement for $\chi^{(3)}$ materials is *optical transparency*. In linear optics the attenuation of light is governed by Beer's law $I(z) = I_0\, e^{-\alpha z}$, where $I(z)$ is the intensity at position z along the direction of propagation, and α the frequency-dependent absorption coefficient. Since many NLO effects and devices depend on a high power of I, absorption artifacts are amplified. If the relevant device variable is the phase shift $\Delta\Phi$ and the maximum length L is limited by Beer's law to be of the order of $1/\alpha$, then

$$\Delta F_{\max} = \frac{2\pi n_2 \bar{I}}{\lambda\alpha} \tag{20}$$

with $\bar{I}$ a mean intensity that takes account of attenuation. The figure of merit is $W = n_2/\lambda\,\alpha$, which should be maximized (not just n_2). A given material has a maximum in W at a wavelength λ_{opt} owing to the wavelength dependence of n_2 and α.

Two other important qualities are *fabricability* and *stability*. For single-mode optical interactions, as in silica optical fibers, materials must be amenable to channel waveguide fabrication. Silica optical fiber is an example of an optimized linear optical signal delivery system, for which an advanced waveguide technology has been developed (→ Fiber Optics, Chap. 3.5.). Similar developments are needed to make NLO materials viable for signal processing unless focal plane switching and free space interconnection approaches develop rapidly. Techniques that have been investigated include evaporation, metal oxide chemical vapor deposition, molecular beam epitaxy, ion sputtering, reactive ion etching, spin coating, Langmuir – Blodgett casting, laser ablation, and photobleaching. The stability of materials for $\chi^{(3)}$ applications is of concern, since these materials are subjected to high light intensities. For polymers and organic crystals, stability to oxidation and high light intensity is uncertain especially under the demanding conditions that devices can experience (high temperature, high pressure, etc.).

Figure 4. Apparatus for performing d.c. Kerr effect measurements on materials
The applied voltage results in a small rotation of the polarization vector of the light and thus in transmission through the analyzer.

4.2. Measurement of $\chi^{(3)}$ Properties

Studies of $\chi^{(3)}$ materials are of two types, frequency domain (dispersion) and time domain (dynamics). $\chi^{(3)}$ spectroscopy is used to study states of a system that are inaccessible to linear optical spectroscopy, owing to quantum electrodynamical selection rules. Studies on organic molecules have been performed with $\chi^{(3)}$ spectroscopy to investigate the symmetries of excited states [45]. Practically, the dispersion of $\chi^{(3)}$ coupled with the dispersion of $\chi^{(1)}$ determine the most useful spectral region of a given material.

Dynamic studies of $\chi^{(3)}$ materials have become prevalent since the advent of subpicosecond and femtosecond laser sources. Measurements of the speed of $\chi^{(3)}$ effects are important because they help to earmark materials for appropriate applications and devices. Third-order materials with large subpicosecond responses are sought for all-optical computing.

Since the d.c. Kerr effect does not rely on the presence of laser light, it was the earliest method for measuring third-order NLO properties [17]. The d.c. Kerr effect measures the off-diagonal elements $\chi^{(3)}_{1221}$, $\chi^{(3)}_{1212}$, and $\chi^{(3)}_{1122}$ that produce polarizations which are orthogonal to one or more of the applied fields. The experimental setup requires a high-voltage source, two polarizers, and a light source (Fig. 4).

Third harmonic generation (THG) is a direct, single-beam method for measuring the purely electronic part of $\chi^{(3)}$, usually $\chi^{(3)}_{1111}$ $(-3\,\omega;\omega,\omega,\omega)$ or equivalently the microscopic third-order nonlinear susceptibility, γ. This makes it useful for fundamental studies of materials, and THG measurements do not require state-of-the-art lasers or multibeam alignments. The Maker fringe technique is used, which determines the two unknowns, $\chi^{(3)}_{1111}$ and the coherence length. Difficulties include the requirement for a large transparency window in the material, and connection between THG measurements and n_2.

The optical Kerr effect (OKE) has been used to measure n_2 of materials [46], and the same tensor components can be measured as in the d.c. Kerr effect. Pump – probe techniques are used which are useful for time domain studies. In orientable media most of the OKE response comes from induced birefringence resulting from the linear polarizability anisotropy of the molecules or atoms in the medium; only a small portion of the response comes from γ_{el}, except for subpicosecond pulses.

Four-wave mixing, nonlinear interferometry, self focusing, and saturable absorption have all been used to measure $\chi^{(3)}$ or n_2. Degenerate four-wave mixing is used in both phase-conjugate and forward scattering geometries and is popular because it is self-phase-matching and signals are large due to resonant enhancement in most materials. This technique also lends itself readily to time domain studies. Because of the difficulty of analyzing the data, self focusing has seldom been used to measure n_2, but improvements in laser beam shapes have led to some research in this area [47]. Nonlinear interferometry has been used to measure third-order NLO properties [48]; elimination of the effects of artifacts (e.g., sample heating, air currents, and

vibrations) is difficult. Through the Kramers–Kronig relations, saturable absorption measurements can be related to resonant n_2 or $\chi^{(3)}$. Typically, resonant $\chi^{(3)}$ values estimated in this way can be six to ten orders of magnitude larger than their nonresonant counterparts.

4.3. Inorganic Materials

Glasses and Ionic Crystals. Some of the earliest NLO measurements were performed on glasses to find materials with low n_2 values that would not self focus in a laser cavity. The microscopic motion responsible for n_2 in glasses and in the majority of ionic crystals (e.g., LiF and NaCl) is mainly electronic and ultrafast. Furthermore, most of these materials have high transparency, making them suitable for high-power optical systems. A waveguide technology exists (optical fiber) for fused silica that makes it a viable material for optical device demonstrations.

Table 4 shows n_2 and n_0 values for some glasses and ionic crystals [48,49]. There is a rough correlation between the values of n_2 and n_0, indicating a monotonic relationship between $\chi^{(3)}$ and $\chi^{(1)}$. Although fused silica has a small value of n_2, its absorption in the near infrared (1.3 µm) is so small ($\alpha \approx 10^{-8}$ m) that its W parameter (Section 4.1) is large.

Research continues to identify materials with low n_2 values for ultrahigh-power applications like laser fusion. A low n_2 is important for minimizing self focusing. Some of the initial triumphs in all-optical processing were made in optical fibers since they constitute an ideal optical waveguide capable of supporting high peak power pulses over long distances. An example of an all-optical switch in silica optical fiber is a directional coupler in which switching between two cores of a dual core fiber occurs < 500 fs [20].

Table 4. Values of n_2 for glasses and inorganic crystals at 1.06 µm

Material ∗	n_0	n_2, 10^{-19} m^2/W	Method of measurement ∗∗
Glass (SF-6)	1.77	2.2	NI
Silicate glass (FR-5)	1.686	0.52	NI
Borosilicate glass (BK-7)	1.517	3.42	NI
PbF_2	1.769	17	NI
KH_2PO_4	1.468	0.29	NI
Fused silica	1.458	0.27	NI
NaCl	1.5312	0.43	FWM
KBr	1.5435	0.80	FWM
Fused silica	1.4496	0.25	FWM
SiO_2 (quartz(o))	1.5342	0.31	FWM
ZnO(o)	1.99	5.30	FWM
TiO_2	2.48	9.5	FWM
$KTiOPO_4$	1.74	1.38	FWM
ZnS(o)	2.29	8.65	FWM
CdS(o)	2.33	54.6	FWM

∗ (o) denotes the ordinary optical axis of the material.
∗∗ NI = nonlinear interferometry; FWM = four-wave mixing.

Semiconductors. Semiconductors attracted intense interest as all-optical materials after optical bistability and differential optical gain were observed in thin etalons of GaAs [50]. (An etalon is formed by placing two partially reflecting surfaces parallel to one another to form a Fabry–Perot interferometer). Refractive indices of semiconductors (n_0 and n_2) are listed in Table 5. Gallium arsenide has many advantages for optical processing because it is simultaneously an electronic material, an electro-optic material, a lasing medium, and an all-optical material. However, GaAs has drawbacks such as instability and a large absorption coefficient when n_2 is large. Some of these advantages and diffi-

Table 5. Values of n_0 and n_2 for semiconductors

Material	λ, µm	n_0	$\lvert n_2 \rvert$, 10^{-17} m^2/W
Nonresonant			
GaAs	1.06	3.2	3.0
AlGaAs	0.81	3.0	40

∗ DREAM = depletion region electroabsorption modulator

culties also apply to multiquantum well (MQW) GaAs – AlGaAs structures (see Section 3.1).

The n_2 values of nonresonant semiconductors are not unusually large. However, when semiconductors are probed near the band gap (the energy difference between the conduction band and the valence band), huge enhancements in $\chi^{(3)}$ are achieved. Mechanisms leading to these enhancements include phase – space filling (an exclusion principle effect), the Burstein – Moss shift, and excitonic nonlinearities. An exciton is a hydrogen-atom-like entity consisting of an electron in the conduction band bound to a "hole" in the valence band of a semiconductor. Excitonic nonlinearities are not present at room temperature in bulk semiconductors since the thermal agitation breaks up the excitons. In MQWs the confinement in the direction perpendicular to the plane of the MQW stabilizes the excitons, so that excitonic nonlinearities are possible at room temperature.

Several other semiconductors besides GaAs have demonstrated large NLO effects. The value of n_2 for InSb is very large in the infrared (10.6 μm), and has been used to make a multistable device (a device that has more than one stable output state for a given input state) [51]. Increasing interest has been devoted to semiconductor microcrystallites embedded in glass (e.g., CS 3-68 and CS 3-67, Table 5), since these systems are good approximations to quantum dots [52]. Quantum dots are three-dimensional confined structures and can be treated theoretically with the particle-in-a-box model of quantum mechanics.

Semiconductors are now being engineered with confinement effects and doping (as in GaAs – AlGaAs *n-i-p-i* structures [53]) to optimize nonlinearity with respect to absorption and thermal effects. The electronic capabilities of semiconductors make hybrid systems like self electro-optic devices (SEEDs) possible.

4.4. Organic Materials

In the 1980s research into the NLO properties of organic media grew rapidly due to the large, ultrafast NLO effects observed in organic polymers, the ability to modify molecules and enhance their nonlinearities through chemical synthesis, and the compatibility between waveguide technology and organic thin film formation techniques. Organics are promising materials for $\chi^{(3)}$ applications, but electronic low-intensity bistability and optical switching have to be observed in organic media. Generally, organic media are desired that are readily synthesized and fabricated, and have an ultrafast response time. Values of n_2 for various organic substances are listed in Table 6 (see next page). Improvements in lasers and chemical synthesis have brought all-optical processing devices based on organic materials closer to realization.

Origin of Nonlinearity. The $\chi^{(3)}$ effects in organic molecules are primarily attributable to the large delocalization of π-electrons in conjugated molecules. Delocalized electrons can produce nonlinear effects because they constitute an interacting system. For example, anharmonic motion in one electron induces anharmonic motion in other conjugated electrons. The theoretically predicted superlinear dependence of $\chi^{(3)}$ on conjugation length for a one-dimensional conjugated chain has been observed. Since the electrons in the π-orbitals are delocalized over the entire conjugation length, the electron cloud can be readily distorted and at high speeds. Nonlinear optical effects in organic molecules do not involve real excitation of the molecule into one of its allowed states, but rather "virtual" excitations that decay in femtoseconds.

Organic media exhibit large resonantly enhanced n_2 values when a combination of applied frequencies approaches an eigenfrequency. This is important because it allows appreciable NLO effects with modest laser input powers. However, the response time also increases and the tradeoff between enhancement of n_2 and an attendant increase in absorption (which may damage the material) is not as good as for semiconductors. This is because the cooperative effects associated with the band gap in semiconductors (e.g., exciton and biexciton formation and propagation, Coulomb screening, and phase space filling) are weak in most organic media. Resonant n_2 values for semiconductor MQWs (2×10^{-8} m^2/W) are three to four orders of magnitude larger than the largest observed resonant electronic n_2 value in an organic molecule (silicon naphthalocyanine, 10^{-11} m^2/W).

Table 6. Values of n_2 for organic materials

Material	λ, µm	n_2, 10^{-18} m^2/W	Method [a]
Carbon disulfide	1.06/0.53	5.2	OKE
Nitrobenzene	0.694	3.7	OKE
Benzene	1.06/0.53	1.7	OKE
PTS – PDA [b]	1.91/0.64	178	THG
Poly-TCDU – PDA [c]	1.91/0.64	45	THG
2-Methyl-4-nitroaniline	1.06/0.532	58	DCSHG
Poly-4BCMU – PDA [d]	0.63	10	DFWM
Polyacetylene	1.91/0.64	2000	THG
Poly(3-methyl-4′-octyl-2,2′-bithiophene-5,5′-diyl)	1.91/0.64	380	THG

Ferrocene	1.06	10	SF
BBL [e]	1.06	148	DFWM
Platinum phthalocyanine	1.06	1580	DFWM
Polysilane	1.9/0.64	18	THG
Fluoroaluminum phthalocyanine	1.06/0.36	439	THG
Azo dye 25/MMA 75 [f]	2.05/0.7	12.4	THG

[a] OKE = optical Kerr effect; THG = third harmonic generation; DCSHG = d.c. second harmonic generation; OFWM = degenerate four-wave mixing; SF = self focusing. [b] *p*-Toluenesulfonate – polydiacetylene. [c] Poly(5,7-decadiyne-1,12-diol-bisphenylurethane) with the side group – $(CH_2)_4OCONH\text{-}C_6H_5$ – polydiacetylene. [d] Poly(4-butoxycarbonylmethylurethane) – polydiacetylene. [e] Poly{(7-oxo-7,10*H*-benz[de]imidazo [4',5′:5,6] benzimidazo [2,1-a] iso-quinoline-3,4:10,11-tetrayl)-10- carbonyl}. [f] Copolymer of an azo dye with methyl methacrylate in a 25 : 75 ratio.

Small Molecules. Liquids consisting of small molecules (e.g., carbon disulfide, benzene, and nitrobenzene) have fairly large n_2 values. Many NLO effects were first observed in these systems and they continue to be of interest for studying new phenomena and as standards. Carbon disulfide is one of the few materials whose absolute n_2 value (Table 6) is known with $> 30\,\%$ accuracy. The optical Kerr effect is used to study the structure and dynamics of organic liquids at short time scales (femtosecond pulses). With pulses longer than a few tens of picoseconds, the n_2 of organic liquids is mainly due to nuclear orientation and only a small part is attributable to electronic motion since the conjugated bond lengths of these materials are short.

Large Molecules and Polymers. The first large organic molecules to be studied for NLO effects were phthalocyanines [54] and biological molecules such as *trans*-retinal [55]. Phthalocyanines are good saturable absorbers and are used to Q-switch ruby lasers; however, in their pure form they are not very soluble in any solvent. This is a frequent problem with highly conjugated molecules, and progress in organic NLO depends on increasing the solubility of the chromophoric units.

Interest has centered on polyacetylenes [*25067-58-7*] and polydiacetylenes because of their large n_2 values in the near infrared (Table 6), which make them suitable for optical fiber applications. Single crystals of the polymer made from *p*-toluenesulfonate and 2,4-hexadiyne-1,6-diol (PTS – polydiacetylene [*32535-60-7*]) have been studied by third harmonic generation [56], and techniques have been developed for forming Langmuir – Blodgett films from polydiacetylenes. Some soluble polydiacetylenes are now available, and all-optical phase modulation has been demonstrated in a single crystal of PTS – polydiacetylene [57].

Polyacetylene

PTS – polydiacetylene

The values of n_2 have been measured in a variety of conjugated structures, including phthalocyaninines [58], electro-optic chromophores [59], polysilanes, polygermanes [60], polythiophenes [61], ladder polymers [62], and block copolymers [63] (Table 6). Most of these materials are at an earlier devel-

opment stage than the polydiacetylenes, and have not generally been incorporated in devices. However, electronic optical bistability in a Fabry – Perot cavity containing a thin film of silicon naphthalocyanine oligomers (resonant $n_2 = 10^{-11}$ m^2/W) has been observed [64].

5. Nonlinear Optical Devices and Applications

5.1. Electro-Optic Devices

The linear electro-optic (or Pockels) effect in which the refractive index changes linearly with an applied field originates from a second-order NLO property. It is the simplest and one of the most important NLO effects. The basic physics of electro-optics and its relationships to NLO are described in Chapter 2 (for further details see [65, 66]). Various electro-optic devices utilize the change in refractive index of a dielectric medium with application of an external field as discussed in Chapter 3. The index change can be used to modulate both phase and amplitude of optical waves passing through the medium. An electro-optic modulator is designed to obtain a required depth of modulation with the lowest possible modulation power over the largest possible modulation bandwidth.

A variety of electro-optic devices based on waveguide and through-the-plane designs have been developed. Technical requirements for two representative devices, a waveguide electro-optic interferometric modulator and an electro-optic spatial light modulator (SLM), are described below.

Waveguide Electro-Optic Modulators. Depending on its geometry, a waveguide can allow a beam to travel at a finite number of angles relative to its axis. Most electro-optic devices are based on a single-mode waveguide architecture in which there is only one angle for beam propagation. The ever-increasing need for faster data communication systems necessitates lower frequencies for optical-to-electrical signal conversions and development of optical switching technology to replace traditional electronic switching.

Moreover, telecommunications networks are based on single-mode fibers and any network components must closely match the optical characteristics of these fibers. It is easier to control guided optical waves by electro-optic effects in the single-mode waveguide. Also, because the waveguides have small diameters (a few micrometers) low modulation voltages can generate a large modulating electrical field. This, in turn, generates larger electro-optic effects, decreases the device length, and thus lowers the capacitance and increases the modulation speed. It also allows integration of the devices making them commercially more attractive. The theory of optical waveguides is described in [67, 68]. Fabrication methods of inorganic waveguides are described in [69], see also → Fiber Optics, Chap. 3.

A large number of waveguide electro-optic devices have been developed and are described in [69]. They include the electro-optic directional coupler switch [70], polarization controller [71], frequency shifter [72], polarization multiplexer and demultiplexer [73], and tunable wavelength filters [74].

Figure 5. Schematic diagram of a Mach – Zehnder type electro-optic modulator, where l is the effective length over which switching can occur

The Mach–Zehnder interferometric modulator best illustrates the design principles and material property requirements of electro-optic devices (Fig. 5). The incoming optical beam is divided in two at a Y-junction and then recombined at a second Y-junction. If the phase shift of the divided beams in both arms is identical, they interfere constructively and all the power reappears at the output. If the phase-shift difference between the two arms is π, the modes interfere destructively and power radiates out into the substrate and is lost. Thus, the optical output power can be controlled by an electrical field applied to the modulator via the electro-optic properties of the

waveguide material. Because the electrode spacing can be made very small (ca. 5 µm), relatively small switching powers are needed. The device capacitance is small and the modulator can be operated at very high frequencies (> 1 GHz).

For a $LiNbO_3$ Mach – Zehnder modulator cut perpendicular to the x-axis of the crystal, the switching voltage V_π is related to the operating wavelength λ, the electrode gap w, the electrode length l, and the material properties such as the Pockels constant r_{33} and refractive index n_e through

$$V_\pi = \lambda \frac{w}{n_e^3 r_{33} l G} \tag{21}$$

Here Γ is the overlap constant between the optical beam and the modulating electrical field and is typically about 0.4 for transverse electrodes.

In high-frequency light modulation, the transit time τ of light through the modulator must be taken into account. If the transit time is not negligible compared to the modulation period, the modulation efficiency is reduced due to mismatch in phase velocity between the modulating microwave signal and the optical wave. The transit time limitation is usually overcome by using a traveling wave electrode design where the switching voltage $V_\pi(f)$ or the bandwidth f is determined by the magnitude of the mismatch. The switching voltage $V_\pi(f)$ of a traveling wave modulator with a length l is increased at high frequencies by a factor

$$\frac{V_\pi(f)}{V_\pi} = \frac{\pi T_\omega f}{\sin(\pi T_\omega f)} \tag{22}$$

where $T_\omega = (l/c)(\sqrt{\varepsilon} - n)$ is the transit time mismatch between the copropagating microwave and optical signals, ε is the dielectric constant of the electro-optical medium, and c is the speed of light.

For efficient high-speed modulator applications (i.e., a low modulation power) electro-optic materials must therefore possess a high Pockels constant and a low dielectric constant. Moreover, the square root of the dielectric constant must be as close as possible to the refractive index to produce a large bandwidth. Compared to traditional inorganic materials such as $LiNbO_3$, newly developed electro-optic polymers (Section 3.3) offer a significant advantage in this respect. For example, $|\sqrt{\varepsilon} - n|$ for $LiNbO_3$ is typically about 3.4 and that for polymers is about 0.17, indicating that the potential bandwidth for polymer modulators can be almost 20 times larger than that of $LiNbO_3$ modulators.

A number of commercial $LiNbO_3$ modulators are available with a switching voltage of ca. 5 V and a bandwidth of ca. 4 GHz. Many companies are developing polymer electro-optic modulators; switching voltages as low as 12 V and bandwidths as high as 1 GHz have been reported [75].

Spatial light modulators (SLM) are devices that modify the phase, polarization, amplitude, or intensity of a one- or two-dimensional readout light distribution as a function of space and time [76]. They exploit the inherent parallelism of light and are a key component of optical information processing systems. The modulators vary according to operational principles, information processing functions, and light modulating materials. Materials include membranes, magneto-optic materials, liquid crystals, and electro-optic crystals.

Figure 6. Optically addressed microchannel spatial phase modulator (MSLM)
a) Photocathode; b) Microchannel plate; c) Grid; d) Dielectric mirror; e) Electro-optic modulating material ($LiNbO_3$); f) Transparent electrode

The optically addressed microchannel SLM (MSLM) utilizes a design in which the applied electric field is parallel to the direction of light propagation in $LiNbO_3$ (Fig. 6) [77]. The magnitude of this longitudinal electro-optic effect depends solely on the applied electrical voltage; a large voltage drop (ca. 2 kV) is needed to achieve sufficiently large effects for device operation. A unique feature of the MSLM is the microchannel plate (b) which provides a large electron gain. It contains a number of fine capillaries through which electrons pass. The latter can be accelerated by adjusting the potential at the grid (c). The electrons are then deposited onto the dielectric

Figure 7. Interference phase loop using a microchannel spatial light modulator
a) Electro-optic crystal; b) Dielectric mirror; c) Microchannel plate; d) Photocathode

mirror (d) and generate a two-dimensional electrical field across the modulating material (e). This creates a two-dimensionally distributed optical path in the modulating material which can be read with an optical beam. Figure 7 shows an application of MSLM called an interference phase loop in which the signal beam interferes with itself through a feedback to sharpen its image [78]. The local oscillator laser creates a fixed phase difference in the feedback so that the system can continuously estimate, compensate and conjugate the wave-front phase over π radians. In operation, a signal image is converted into a spatial electron image by the photocathode. The electron image is amplified by the microchannel plate and deposited on the surface of the $LiNbO_3$ crystal. The charge distribution on the surface of the crystal modulates the readout beam via the longitudinal electro-optic effect. The grid between the microchannel plate and the crystal is used as a secondary electron source to erase the image frame.

5.2. Frequency Doubling and Parametric Conversion

Wave interaction of two input beams in a second-order nonlinear medium leads to generation of a third output beam (three-wave mixing). When an optical wave interacts with itself, its frequency can be doubled (second harmonic generation). If the interacting waves have different wavelengths, sum- and difference-frequency generation can result, which are termed parametric processes (Chaps. 2 and 3). With advances in tunable lasers, frequency doubling and parametric conversion processes have become widely used NLO effects for extending the tunable range of coherent sources to UV and IR wavelengths. The source beams generally have a high intensity and a high power conversion can be achieved if the phase-matching condition is met.

Frequency doubling of low-power diode lasers is drawing intense interest. Since data density in optical recording is diffraction-limited, a compact short-wavelength source would allow higher recording density. A 10-mW source is usually required for writing and a 2-mW source for reading in commercial optical data storage systems. To maintain a relatively high optical power density and thus to improve conversion efficiency, the diode laser beam can be confined in a waveguide and phase matching obtained through a number of methods including periodic modulation of the $\chi^{(2)}$ [12, 13].

5.3. Third-Order Nonlinear Optical Devices

Third-order NLO effects are relatively small. Although phenomena such as third harmonic gen-

eration, the optical Kerr effect, self focusing, stimulated Raman scattering [79], and optical phase conjugation [80] have been known since the early stages of NLO, practical devices are still in concept stages and require significant improvement in materials.

Nonlinear Waveguide Coupler. A manifestation of third-order NLO effects is the light-intensity-dependent refractive index n_2 defined in Section 2.1.3. This phenomenon has been used in a nonlinear waveguide directional coupler based on GaAs [81], which has a fairly large nonresonant n_2 (Table 5).

In waveguide couplers, two identical waveguides are in proximity (Fig. 8). The optical beam launched in one guide is transferred to the other guide at an interaction distance characteristic of the device. If the refractive index of the waveguide is intensity-dependent, then the coupler is nonlinear. If the optical beam intensity in one guide is large, the refractive index is changed to such an extent that the mode pattern changes and transfer becomes incomplete or does not occur at all. With GaAs waveguides of $10\,\mu m^2$ cross section and 1.7 mm coupling length, a critical power (the input optical power at which the output power is equally divided between the two guides) of $500\,\mu W$ was demonstrated for $\lambda = 0.85\,\mu m$. A detailed analysis of waveguide NLO device concepts is given in [82].

Figure 8. Two coupled channel waveguides with a nonlinear material in the coupling region, this structure can operate as an all-optical switch

Optical Phase Conjugation. In optical phase conjugation a NLO effect is used to reverse the direction of propagation of a light beam and its overall phase factor. Optical phase conjugation is produced by two standard methods; stimulated Brillouin scattering and four-wave mixing in a NLO medium [83]. When a light source is reflected from a phase-conjugate mirror, the reflected wave carries all the information of the original beam, but retraces its original path regardless of its incidence angle. A general phase-conjugate medium can conjugate a beam with an arbitrary wavefront back to its original path, point by point, irrespective of its incident angle. A phase-conjugate wave is also termed "time-reversed" because it runs along the same trajectory as the original beam but in the opposite direction.

An application of optical phase conjugation is to "anti-distort" a distorted wave in a so-called double pass geometry. A high-quality optical beam can, for instance, be transmitted through a turbulent atmosphere and be made to retrace its own path after reflection from a phase-conjugate mirror. When the beam returns to its point of origin it is therefore free of distortion. A variation of this is removal of distortions in fiber optic cables. In an optical fiber, the image travels in many optical modes. These modes travel different paths, and are out of step by the time they reach the end of the cable. The image can be unscrambled if it is phase conjugated and sent back through the same fiber or another identical link.

In self targeting of radiation, a broad beam from a relatively low-power source is directed in the vicinity of the object that is to be targeted. The object scatters the radiation in all directions, some of it falls on an amplifier placed near the object. As the radiation travels through the amplifier its power is magnified. A phase conjugator at the end of the amplifier creates an "anti-distorted" beam, reflects it back through the amplifier, and a powerful directed beam is thus focused on the object.

Optical phase-conjugate beams can also be used in pointing and tracking of moving objects, image processing, optical computing, interferometry, laser gyroscopes, fiber and satellite communication systems, laser weapon systems, and noncontact photolithography.

5.4. Nonlinear Optics in Optical Fibers

Because silica is a symmetric molecule, silica glass does not normally exhibit second-order

NLO effects. The lowest-order nonlinear effects in silica optical fibers originate from the third-order susceptibility $\chi^{(3)}$. A prominent third-order effect is the intensity-dependent refractive index (Eq. 8). Although n_2 of silica glass is very low ($\approx 10^{-20}$ m^2/W), the glass fiber is an excellent third-order material because the NLO effects can occur over a large length due to its outstanding optical transparency.

Optical Solitons. The term "optical soliton" refers to a special optical wave that can propagate undistorted over long distances and remains unaffected after collision with other solitons.

To form solitons, the optical fiber must have an intensity-dependent refractive index n_2 and an anomalous group velocity dispersion (Section 2.1.3). A light pulse propagating in such an optical fiber is spectrally broadened due to the nonlinearity. However, because of the anomalous dispersion, the broadened pulse is sharpened back to its original shape. Thus, the interplay between n_2 and dispersion maintains the pulse shape over a long propagation distance [84].

An interesting application of solitons in fiber is the soliton laser. Here, an optical fiber cavity is coupled to a synchronously pumped, mode-locked dye laser. The pulse width of the laser can be precisely controlled by varying the fiber length [85]. Pulses as short as 50 fs have been produced by this technique.

The performance of high-speed fiber optic telecommunication systems is generally limited by pulse broadening due to dispersion. Since solitons maintain their pulse widths over long distances, soliton-based communication systems have been proposed. Transmission of 55 ps solitons over 400 km in optical fibers has been demonstrated [86].

Second Harmonic Generation. Silica optical fibers can generate a significantly large second harmonic of a 1.06 µm pump beam if the fiber is illuminated with the pump radiation for several hours [87]. The mechanism is not fully understood; it is generally believed that a periodic ordering of some entity such as color centers or defects along the fiber length occurs resulting in a phase-matching condition [84].

1. Introduction

Definition. An unambiguous definition of nonwovens has not yet been found. In the broadest sense nonwovens are understood to mean textiles that are manufactured by nonconventional technologies. They are made of fiber webs which are bonded together as a result of inherent fiber-to-fiber friction (entanglement), mechanical treatment, heat, or chemical methods.

Nonwovens (Fig. 1 A, see next page) differ from conventional textiles manufactured from yarns [e.g., wovens (Fig. 1 B) and knitted fabrics (Fig. 1 C)] in that they are formed directly from individual fibers. Webs are the starting material for nonwovens (DIN 61 210), and are formed primarily from fibers, possibly with admixture of other fibrous constituents of various types and fiber lengths (e.g., cellulose pulp). The fibers are normally of a limited length, mainly staple fibers (length ca. 30 – 100 mm) that are suitable for spinning into yarn. They may, however, also be only a few millimeters long or of unlimited length (i.e., continuous filaments).

Nonwovens may be produced from staple fibers on a dry basis (dry-laid nonwovens) using methods based on conventional textile technology, or on a wet basis (wet-laid nonwovens) using methods based on conventional paper technology. Spunbondeds are not formed from staple fibers, but from continuous filaments that are produced by melt spinning.

The expression "bonded fabrics" was initially adopted in the United Kingdom. However the broader term "nonwoven fabrics" used in the United States has now found widespread usage. The terms "nonwoven textiles" or simply "nonwovens" are also encountered. These terms all denote textiles that are not woven. In Eastern bloc countries the term "textile composites" is also used to denote nonwovens that include textiles manufactured from fibers by sewing methods. Textile composites are, however, otherwise understood to be fabrics composed of at least two layers or plies bonded together. Nonwoven composites may include yarns as an additional structural element, although the nonwoven character should predominate. Fabrics made of fibrillated plastic films are not included in DIN 61 210.

Classification. The classification of nonwovens according to their method of manufacture has been adopted worldwide (Fig. 2). DIN 61 210 also specifies characteristic properties of nonwovens that can also be used for their classification.

Historical Development. Although nonwovens had been known since the 1920s, they only became important during World War II. The lack of high-quality cotton and viscose fibers during

Figure 1. Comparison of a spunbonded nonwoven (A), a textile fabric made of yarn from staple fibers (B), and a knitted fabric of filament yarn (C)

the war led to attempts to bond poorer quality fibers that were not suitable for spinning as yarns and to discover new applications for these products. In the United States disposable products were developed (e.g., cleaning cloths, handkerchiefs, dressings and bandages, and sanitary and hygiene articles). However, as early as 1944 the Minnesota Mining and Manufacturing Company began producing nonwovens for electrical insulation applications; compliance with a specific quality standard was therefore essential.

Pioneers in the Federal Republic of Germany included Vorsteher and Bunger, Wuppertal, who claimed a patent for the production of dry-laid nonwovens for the shoe industry (e.g., for interlining, reinforcement, and insoles). " Capama-Stoffe" is the trademark of the equivalent product now manufactured by Franz Kalff, Stotzheim.

A nonwoven leather imitate was developed by Ten Cate and Nottebohm in 1930. The manufacturing process for this product was taken over by Carl Freudenberg, Weinheim in 1936. The fiber raw materials were cottonized hemp and viscose staple; natural rubber latex and poly(vinyl acetate) dispersions were used as binders. The production of " Vlieseline" (an interlining for the clothing industry) began in 1948. The production of durable " Vileda" domestic cloths followed in 1950; " Viledon" nonwovens for technical applications appeared shortly after.

In 1933 C. H. Dexter and Sons in the United States were the first to produce wet-laid nonwovens from vegetable-type fibers on a Fourdrinier paper machine that were used for tea bags. Manila hemp was subsequently used and was processed on more suitable rotary formers or inclined wire machines.

In 1964 Feldmühle (Oberlahnstein) produced wet-laid nonwovens on an inclined wire machine; the products were used as disposable sheets in casualty departments and isolation wards in hospitals.

In 1965 spunbonded nonwovens manufactured by Carl Freudenberg and Du Pont appeared on the market.

Du Pont's most important patent, relating to water entanglement, was granted in 1968. In 1970 ICI began production of thermobonded nonwovens based on the polyamide 6/6.6 Heterofil fiber. In the early 1980s microfiber nonwovens manufactured by the melt-blown method patented by Exxon began to appear on the market.

Figure 2. Technological classification of fiber webs – nonwovens

2. Raw Materials

2.1. Fibers [14–19]

The wide range of manufacturing methods for nonwovens permits the use of all commercially available fibers, natural fibers, mineral fibers, as well as man-made inorganic and organic fibers.

Synthetic organic fibers predominate; polypropylene fibers are the most important, followed by polyester, viscose, and polyamide fibers. Synthetic inorganic fibers (e.g., glass or mineral fibers) are far less important. These fibers are described elsewhere in detail (→ Cellulose ; → Fibers, 4. Synthetic Organic; → Fibers, 5. Synthetic Inorganic). The consumption of the most important fibers for the nonwovens industry is summarized in Table 1.

The fibers are incorporated into the nonwovens either in pure form or as mixtures in accordance with the required end-use properties and the manufacturing methods employed. Polypropylene, polyester, and viscose fibers account for more than 80 % of consumption in Western Europe. Polypropylene fibers exhibit the highest growth rate due to sharply rising capacities in spunbonded nonwovens and thermobonded staple-fiber nonwovens for hygiene and medical applications. Polyester also exhibits a marked growth rate due to increased demand for nonwovens in technical applications (e.g., filtration and interlinings for clothing).

Table 1. Summary of fiber consumption for nonwovens in Western Europe, the United States, and Japan (10^3 t/a)

Region	1984	1985	1986	1987
Western Europe [a]

[a] Including spunbonded nonwovens, according to the European Disposables and Nonwovens Association (EDANA), Brussels.
[b] Consumption of staple fiber, according to the Fiber Economics Bureau, excluding spunbonded nonwovens.
[c] Consumption of staple fiber, excluding spunbonded nonwovens.

The major proportion of fibers processed into nonwovens in 1987 consisted of regular staple

fibers for dry-laid and wet-laid nonwovens. The proportion in Western Europe was ca. 67 %, in the United States ca. 70 %, and in Japan ca. 65 %. The proportion of spunbonded nonwovens was ca. 31 % in Western Europe, 20 % in the United States, and 24 % in Japan.

Polypropylene fiber has a low density and is hydrophobic. It is used in the form of staple fibers and as filaments in spunbonded nonwovens, particularly nonwovens for diaper top sheets and the medical sector. On account of its resistance to both acid and alkali, it is also used in technical applications such as separators for batteries. On account of its low melting point, polypropylene fiber is ideally suited for thermobonding with heated calender rolls (see Section 3.2.3).

Polyester Fibers. Due to their easy processability as staple fibers, polyester fibers are important in a wide range of nonwovens. They can be bonded by chemical, mechanical, and thermal methods, and are extremely important in applications requiring a durable nonwoven (filters, interlinings, coating substrates, insulation materials). Polyester fibers are also a starting product for high-strength spunbonded nonwovens used as support materials for tufted carpets or bitumen roof substrates.

Polyamide fibers have a very high dry strength, a high flexural elasticity, and an outstanding abrasion resistance. They impart excellent softness to nonwovens in textile applications (e.g., interlinings).

Viscose fibers are derived from the natural polymer cellulose, they are hydrophilic and are used in absorbent nonwovens such as wiping cloths. On account of their nonthermoplastic nature, viscose fibers have become less important because they cannot be processed by modern thermal bonding methods. However, they could attract interest in the future due to increased use in wet-laid nonwovens and in the water entanglement process (see page 14) for manufacturing nonwovens that are environmentally friendly since viscose fibers are readily degradable.

Bicomponent Fibers. Special fibers are becoming increasingly important in nonwovens manufacture for achieving specific properties. Bicomponent fibers composed of different polymers are particularly important in this respect. Figure 3 shows the most common cross-sections of such fibers. Examples of polymer combinations are polyester – copolyester, polypropylene – polyethylene, polyester – polyamide, polyester – polypropylene, and polyamide 6 – polyamide 6.6. One polymer component has a lower melting point than the other. In a sheath – core fiber, for example, the sheath component has a lower melting point than the core. This is exploited in thermally bonded nonwovens. Heating melts the sheath, and bonding is achieved because the fibers adhere to one another and the core remains unchanged as a supporting fiber. In matrix – fibril fibers the matrix components can be chemically dissolved from the nonwoven, leaving the fibril fibers behind. These fibers are used to manufacture synthetic velour materials with a leatherlike character.

Figure 3. The most common cross sections of heterofilament fibers composed of two different polymers (a and b) A) Side-by-side; B) Core and sheath; C) Orange-type; D) Matrix and fibrils

Other Fibers. Other special fibers are used in small amounts for nonwovens. Polyacrylonitrile fibers are used in the filtration sector to remove dust from air because they are more resistant to hydrolysis than polyester fibers. Polyimide, polytetrafluoroethylene, and poly(phenylene sulfide) fibers are used in applications where high thermal resistance is required (e.g., in protective clothing or for hot gas filtration).

Fiber Properties Depending on the fiber fineness (titer in dtex, 1 dtex = 1 g/10^4 m), the length of the staple fibers varies between 28 and 100 mm: preferably between 40 and 60 mm for dry-laid nonwovens, and between 3 and 20 mm (preferably between 6 and 15 mm) for wet-laid nonwovens. Titers are preferably in the range 1.0 – 6.0 dtex. The most common standard titers are 1.7 – 2.2 – 3.3 dtex. Coarser titers (e.g., 17 to more than 100 dtex) are, however, found in high-bulk fiberfill nonwovens (e.g., for filter mats and abrasive materials) and in spunbonded nonwovens for building construction and civil engineering.

In recent years the category of fine fibers (1.0 – 2.2 dtex) has been extended to include very fine spun fibers (0.2 dtex) which have, for example, been used to produce lightweight nonwovens with good web uniformity and covering power. These very fine fibers are mainly used in mixtures with coarser fibers to improve the appearance of the nonwoven.

Even finer fibers can be obtained by electrostatic spinning and by using the melt-blown process, where the fiber diameter can be adjusted in the range 1 – 8 µm. Spunbonded nonwovens can also be produced with such fine fiber diameters (see page 13).

In the matrix – fibril fibers with a titer of 1.7 – 2.2 dtex, polyamide or polyester fibrils are embedded in a polystyrene matrix. The polystyrene matrix is dissolved, leaving the fibrils with a fineness of ca. 1/100 dtex and a cross section of 0.3 – 1.0 µm. Poromeric velour leather for clothing (Alcantara, Toray; Amaretta, Kuraray) can be produced from these fibers.

Fiber length and fineness are not the only important properties; the cross section, crimp, and shrinkage behavior are also significant.

Synthetic fibers are usually spun with a full, circular cross section, whereas spun viscose fibers have irregular, fissured cross sections with corresponding surface properties. Fiber surface properties affect fiber-to-fiber friction and thus influence the fiber-opening and web-formation processes as well as the shrinkage behavior of the bonded nonwoven. The same applies to synthetic fibers with geometrically simple structures (e.g., hollow fibers or fibers with a triangular, star-, or bean-shaped cross section). A minimum crimp is necessary if the fibers are to be used for production of dry-laid nonwovens. A high crimp is necessary for the manufacture of high-bulk, highly textured nonwovens, with crimps of 20 – 210 per 100 mm and a crimping factor of 10 – 50 (ratio of crimped to drawn-out length). The type of crimp also plays a role in determining the properties of nonwovens; a distinction is made between flat, two-dimensional and spiral, and three-dimensional crimp.

Fiber shrinkage is generally undesirable in nonwoven manufacture; fibers with 1 – 4 % shrinkage are normally used.

Thermoplastic bonding fibers in the homofilament or bicomponent form with widely differing melting points have become extremely important in the manufacture of nonwovens. The fibers should have a relatively broad softening range before the melting point is reached to permit bonding on application of pressure and temperature. In pressure-free bonding in a hot air stream the fibers should not shrink significantly before the adhesion temperature is reached. Fibers with thermoplastic and thus adhesive properties are usually mixed with nonthermoplastic fibers (e.g., viscose) to obtain binder-free nonwovens.

2.2. Binders

Nonwovens can be bonded in different ways. One of the most important methods for dry- and wet-laid nonwovens is the use of adhesive resins, commonly referred to as binders.

According to the European Disposables and Nonwovens Association (EDANA), ca. 31 000 t of binders (in aqueous dispersion, but calculated as dry substance) were used for the production of nonwovens in Western Europe in 1988. Contributions of the relevant binders were as follows: polyacrylates 41 %, styrene – butadiene copolymers 9 %, acrylonitrile – butadiene copolymers 9 %, poly(vinyl chloride) and copolymers 4 %, and poly(vinyl acetate), principally copolymers with ethylene, 23 %. Other binders account for ca. 14 % of the total. Consumption of binders in the United States was ca. 70 000 t in 1988, in Japan consumption was ca. 12 000 t.

The binders are selected according to the required properties of the nonwoven (e.g., softness, wash resistance, absorbency). Practically all film-forming binders can be used. For further

details on the binders described in this section, see → Adhesives.

Polyacrylate Dispersions. Polyacrylates and polyacrylate copolymers are preferred as binders for nonwovens because of the large number of available products and their broad range of properties. The polymers formed from the methyl, ethyl, and butyl acrylates and methacrylates are most important. The hardness and solvent resistance of the polymer decrease with increasing chain length of the alcohol moiety. Polymethacrylates have a higher film hardness than polyacrylates. Polyacrylic acid and polymethacrylic acid are soluble in water and alkali.

Highly cross-linked, water-resistant, solvent-resistant binders are obtained by copolymerizing acrylates with acrylic acid or acrylamide. The acid-containing copolymers can be externally cross-linked by adding zinc oxide, while the amide-containing copolymers can be externally cross-linked with N-methylol compounds such as urea – formaldehyde or melamine – formaldehyde resins. Internal cross-linking occurs if, e.g., *N*-methylolacrylamide is incorporated into the polymer; the addition of a cross-linking agent is then no longer necessary. Self-cross-linking with *N*-methylolacrylamide has become the most important type of cross-linking.

In addition to methyl methacrylate, other monomers (particularly styrene and acrylonitrile) are also copolymerized to modify the handle. In contrast to rubber-type polymers, acrylates do not have carbon – carbon double bonds. They are resistant to light, ageing, and, if well cross-linked, to washing and dry cleaning; they are not, however, as elastic and resilient as rubber-type polymers.

Rubber Latexes. Synthetic styrene – butadiene rubber (SBR) and acrylonitrile – butadiene rubber (NBR) are preferred to natural rubber on account of their high resistance to light, oxygen, and heat. Nitrile rubber polymers are also more resistant to oil, grease, and solvents. They are therefore used for durable household cloths for domestic use and in car care. Styrene rubber latexes are preferred for applications in which discoloration or staining is relatively unimportant and a low consumer price is desired (e.g., disposable articles, carpet backings, and filter mats). Sulfur cross-linking in a vulcanization oven can be avoided by copolymerization of methacrylic acid or acrylamide, which can be cross-linked with zinc oxide or aminoplasts on drying. Copolymers with reactive monomers (e.g., *N*-methylolacrylamide) are also available and self-cross-link on heating.

Of special interest are latexes that are made to coagulate at 40 – 60 °C by adding sensitizing and stabilizing agents; alternatively such latent coagulation properties can be imported to the latex polymer by the manufacturer. They are used to impregnate heavyweight webs and suppress the migration of the binder dispersion to the web surface that would otherwise occur on drying. Depletion of binder in the web interior can lead to delamination of the nonwoven under bending and buckling stress. As a result of coagulation at relatively low temperature (40 – 60 °C) the binder remains uniformly distributed over the web cross section. In the sensitization systems coagulation is initiated by raising the temperature and/or by altering the pH. The method is used particularly in the manufacture of leather imitates (e.g., substrates for coatings or heel-grip linings for shoes).

Poly(Vinyl Ester) Dispersions. The most important poly(vinyl ester) dispersions for web bonding are composed of copolymers of vinyl acetate and ethylene, and of vinyl acetate, vinyl chloride, and ethylene. The hardness of the binder can be adjusted by a suitable choice of the monomer ratios. A high ethylene content leads to soft binders, a high vinyl acetate content gives moderately hard binders, whereas vinyl chloride produces very hard binders.

As described for acrylate dispersions, thermally self-cross-linkable products or products that can be cross-linked with additives are obtained by incorporation of monomers bearing functional groups. These products have a very high water resistance and a satisfactory solvent resistance. Thermosensitive adjustment is also possible by using a suitable choice of dispersion stabilizing system and thermosensitizing agent.

Vinyl chloride copolymer dispersions have a good thermal sealability and a high-frequency weldability. These binders also provide a good basis for flame protection.

Poly(vinyl ester) binders are used for hydrophilic or hydrophobic hygiene and hospital

nonwovens, domestic wiping cloths, weldable fiberfill materials in automobile construction, flame-resistant filter media, and needle-felted flooring materials of low flammability.

Poly(Vinyl Alcohol). Poly(vinyl alcohol) is prepared by partial or total saponification of poly(vinyl esters), especially poly(vinyl acetate); film properties (water solubility, hardness, and strength) vary correspondingly. Cross-linking with urea or melamine – formaldehyde precondensates results in acceptable washfastness.

Polyurethane Dispersions. The impregnation of nonwovens (mostly needled) with polyurethanes dissolved in dimethylformamide, has been used since the 1960s for synthetic shoe upper materials and since the 1970s for synthetic velour leather for clothing. The binder range has been expanded to include aqueous polyurethane dispersions. These surfactant-free dispersions can be thermosensitively adjusted without difficulty. However, their high price has prevented large-scale use in the nonwovens sector.

Aminoplast and Phenoplast Precondensates. The majority of aqueous binders for nonwovens are emulsions and dispersions of elastomers and thermoplasts. Urea – and melamine – formaldehyde resins are used as aqueous precondensates for bonding glass fiber nonwovens and as cross-linking agents for reactive binders. Phenol – formaldehyde resins are used as binders for relatively coarse-fibered abrasive nonwovens with variable abrasive grain composition. In insulation mats for the automobile sector the phenol resin is generally added in powder form.

Articles produced from aminoplast and phenoplast precondensates, and to a lesser extent, self- cross-linking binders that have N-methylol groups contain free formaldehyde. Formaldehyde levels are restricted for health reasons, particularly in the clothing industry. Formaldehyde concentrations are measured by precisely defined methods. Table 2 gives an overview of existing regulations and free formaldehyde limits in various countries. In the Federal Republic of Germany the upper limit for textile fabrics in general is 1500 ppm. The formaldehyde concentration of adhesively bonded nonwovens can be kept well below this limit and is normally 75 – 300 ppm; fiber-bonded, nonfinished nonwovens are formaldehyde-free.

3. Production Processes

Two main processes based on textile processing methods are used to manufacture nonwovens, the primary products are dry-laid fiber webs formed from staple fibers and spunbondeds (Fig. 2). The two processes account for 80 % of the total world nonwovens market.

Table 2. Free formaldehyde limits in textile fabrics (including nonwovens)

Country	Regulation	Maximum concentration, ppm	Test method
Japan	Law 112	Group 1: up to 1000 (outerwear, protective wear linings) Group 2: up to 300 (shirts, blouses, nightgowns) Group 3: up to 75 (underwear, socks) Group 0, baby clothing	acetylacetone
United Kingdom	company-specific regulations (e.g., Marks & Spencer)	(300) – 700, (700) – 1000, new 500	Shirley Bulletin 48, 17, 1975; AATCC ∗ 112, 1978

∗ AATCC: Association of American Textile Chemists and Colorists.

The wet process yielding wet-laid nonwovens is based on conventional paper technology and accounts for ca. 10 % of the market.

A further manufacturing technique, described particularly in the American specialist literature, is the dry paper process (air-laid pulp). A more recent development is the admixture of short fibers to cellulose pulp, this yields products which, like wet-laid nonwovens, are difficult to distinguish from paper [33].

3.1. Web Formation

3.1.1. Dry Web Formation [20–30]

This section describes dry processes for forming card webs and fibrous webs that start with spun fibers (generally synthetic fibers) of finite length, i.e., staple fibers. Fiber fineness ranges between 1 and 30 dtex, and fiber length between 20 and 120 mm.

In contrast to conventional yarn manufacture, fiber mixtures of different composition are processed to satisfy subsequent application criteria. Fiber blending, involving opening and mixing, is therefore subject to particularly stringent requirements. Two main routes are used:

1) Decentralized: an individual, web-forming line is preceded by a continuously operating opening and mixing line
2) Central: the fiber mixtures are prepared in batches on a central line and pneumatically conveyed to the fiber bins of the individual web-forming lines

The following factors are of importance for the design of the lines: output (in kilograms per hour), batch size, frequency of batch replacement, number of fiber components, quality requirements, and degree of automation.

The considerable increases in output of web-forming lines achieved in recent years have placed more stringent requirements on the degree of opening (loosening) and mixing; a high degree of flexibility and high productivity of the lines are also needed.

Blending involves the following steps:

1) Removal of the bale packaging,
2) Unpacking and opening the individual bales,
3) Weighing and metering the individual fiber components according to the formulation,
4) Mixing,
5) Storage, and
6) Opening

Depending on requirements and machine design, various functions (e.g., mixing and storage) can be combined in a single machine; one function can also be performed by several machines (e.g., opening). A highly uniform mass distribution along the length and in the cross direction is required in the end product, flock feed to the web former must therefore be precisely controlled. Conventional hopper feeders are equipped with electronic scales to ensure that a uniform, precise amount of flock is discharged per weighing cycle onto the conveyor belt of the web former. Volumetric chute feeding has become more important as a result of increasing outputs and machine widths. With volumetric chutes, a uniform specific density is achieved along the length by regulating the charging height and the compaction of the fiber flocks. The flock can be compacted mechanically in a so-called vibrating chute or with air. The latter method has the additional advantage of a self-regulating width distribution of the flocks due to discharge of air from the chute feed. Adjustable segments in the rear wall of the chute feed provide an additional means of modifying the web profile across the machine width.

Mechanical Web Formation on Cards. Carding is still the most economically important web-forming technique and has the largest market share. The carding machine opens, mixes, and homogenizes the flocks. It also orientates the individual fibers and converts them into a coherent web with a defined specific density. The design and construction of a roller card is described in DIN 64 118. In its simplest form it comprises feed rolls, licker-in rolls, a main cylinder, workers, strippers, a doffer, and take-off rolls. In modern machines all rolls have a metallic card clothing; the carding or take-off effect is influenced by teeth geometry, teeth density, teeth settings, relative roll speeds, and roller gaps.

Recent developments have been aimed at increasing productivity (e.g., by incorporating several doffers) and at influencing the degree of orientation of the fibers in the carded or fibrous web (e.g., by incorporating randomizing

rollers and/or compacting rollers). Changing the fiber orientation improves the machine direction – cross direction (MD/CD) ratio of the web strengths and results in high line productivity while maintaining the required quality properties. This primary product is also termed "tangled web", especially in the hygiene applications sector.

Further improvements include an increase of machine widths up to 4 m, and computer-aided, programmable line control. Line speeds of 150 – 200 m/min have already been achieved under continuous operation. The roller card can process practically all synthetic and natural fibers of different fineness. This fact combined with its substantially higher productivity have led to the predominance of the roller card in the nonwovens sector over the conventional flat cards used in cotton mills. The latter machines are only used in a few special fields.

The unidirectionally or randomly oriented fiber web (weight ca. 10 – 20 g/m^2) produced by the carding machine is laid on a conveyor belt; webs from two or more cards are generally laid one on top of the other (Fig. 4). The preferred orientation is in the machine direction. In bonded webs this orientation can produce a tensile strength in the MD that is up to ten times greater than that in the CD.

The carded web is taken up by a cross lapper which is equipped as a camelback with an oscillating laying device (Fig. 5), or with a horizontal laying device (Fig. 6), and is laid in a zig-zag pattern on the apron. The resultant cross orientation of the web can be varied by changing the laying angle and take-off speed.

Unidirectional and cross laying (Fig. 7) can be combined to form webs with uniform tensile strengths in all directions.

Aerodynamic Web Formation [31–34]. Pneumatic (aerodynamic) web formers have the same objective as carders, namely the production of randomized webs with isotropic strength properties. Almost all commercial machines are based on the principle shown in Figure 8. The randomized mass of fiber flocks is mechanically opened with a high-speed saw-toothed drum. The centrifugal force and a supporting air current dislodge the fibers from the sawteeth. The air current conveys the fibers to a delivery system (a suction drum or suction belt) where the web is formed under free-fall (with compressed air and/or suction) or in a closed system.

Figure 8. Basic principle of aerodynamic web formation (courtesy of Textilmaschinenfabrik Dr. Ernst Fehrer AG)

The stringent requirements concerning the blending of the fiber flocks and a uniform mass distribution during feeding (see introduction to this Section 3.1.1) are of particular importance because substantial opening and mixing do not occur in the aerodynamic web former.

Aerodynamic web formation is suitable for medium-fine to coarse fibers with a uniform titer. Suitability for fine fibers is limited because fiber mixtures tend to separate in the air current and during take-off. The process is particularly suitable for heavier, voluminous webs. An advantage is the low delamination tendency due to the three-dimensional, rooftile-like arrangement of the fibers in the web.

The aerodynamic web former in Figure 9 consists of four high-speed drums arranged in series. Doffing of the fibers takes place at four points by centrifugal force and is assisted by the suction effect of the screen belt. Additional carding is achieved by pairs of workers/strippers arranged above the carding drums.

3.1.2. Wet (Hydrodynamic) Web Formation [35–40]

The wet web formation process is based on paper manufacture technology. Short staple fibers (length generally < 20 mm) are dispersed in water, frequently together with cellulose pulp to give a dispersion with a density of 0.1 – 0.8 g/dm^3. This concentration is ten times more dilute than that used for paper manufacture. The fibers are deposited onto an inclined (Fig. 10) or rotary screen (Fig. 11) to form the web. Water is then uniformly sucked off over the machine width through suction boxes located be-

Figure 9. The K21 random card (courtesy of Textilmaschinenfabrik Dr. Ernst Fehrer AG)
a) Suction boxes; b) Screen belt; c) Worker rolls; d) Main cylinder

neath the screen. Deposition of the fibers on the screen is controlled by the filtration resistance of the web that builds up during the process. The inclined screen permits higher outputs and larger machine widths than the rotary screen, in which the layout and arrangement of the suction boxes and the sheet-forming zone are restricted. Inclined screen equipment such as the Hydroformer manufactured by Dorries (FRG), the No-Wo-Former manufactured by Bruderhaus Maschinenfabrik (FRG), and the Delta-Former manufactured by Sandy Hill Corp. (USA) are widely used.

Figure 10. Principle of web forming on an inclined screen a) Inclined screen; b) Suspension; c) Suction box; d) Suction-free zone

Fiber orientation can be regulated by adjusting the web-forming speed as well as the suspension rates. A randomized web is formed if the two rates are the same, whereas a difference in the rates favors the formation of a unidirectional web.

The production rate depends on the water drainage and the desired weight. Machine manufacturers cite rates of 30 – 300 m/min for webs of 10 – 100 g/m^2. Up to 1500 g/m^2 are possible depending on the fiber material. The productivity of a 4.5-m wide machine is about 12 000 t/a.

The length of the processed staple fibers depends mainly on the fiber titer. Fine textile fibers of 1.7 – 3.7 dtex should be 6 – 15 mm long; from 5 dtex upwards, lengths of 20 – 25 mm are possible. Use of crimped fibers is limited on account of the danger of entangling; wet-laid nonwovens are therefore less voluminous and "textile-like" than dry-laid nonwovens. Large amounts of cellulose pulp can, however, be added without excessively lowering the strength. Wet processing can also be employed with short, brittle mineral fibers, which are mechanically destroyed on carding machines. Investment costs for a high-performance wet-forming machine are roughly five times higher than those for the dry process. This is, however, offset by the high productivity and lower labor costs in comparison to the dry process, although the economy of the high-performance machine is dependent on good design.

The binder can be precipitated on the fibers (preferably cellulose pulp) prior to web formation by coagulation in the mixing vat. Binders are, however, usually applied by spraying, padding, foaming, screen printing, or saturation; these methods are also used with dry-laid webs (see Section 3.2.2). The webs are dried on a suction drum or can dryer.

Developments are aimed at optimizing web formation. Multilayer webs, in which each layer is formed from different raw materials, can be obtained by altering the feeding system. New types of binder fibers permit thermal bonding on a suction drum dryer for more sophisticated applications. Water entanglement allows production of strong, more drapable, wet-laid textile nonwovens. The high web-forming rates that can be achieved in the wet process permit the admixture of ultrafine, synthetic fibers up to a titer of 0.6 dtex without adversely affecting process economy.

In the medium term, a trend towards the use of biologically degradable fibers (e.g., viscose fibers) can be detected which may also give a new stimulus to wet web-forming.

3.1.3. Spunbondeds [41–53]

In contrast to dry- and wet-laid nonwovens (Sections 3.1.1 and 3.1.2) which are made from staple fibers, spunbondeds are spun directly from thermoplasts (e.g., polyethylene, polypropylene, polyesters, polyamides, or polyurethanes) by the melt spinning process (→ Fibers, 3. General Production Technology, Chap. 6.).

As in conventional melt spinning, the molten polymer is extruded and forced through spinnerets. Thread forming and simultaneous drawing require high drawing rates comparable to those used in high-speed spinning processes for synthetic fiber production (up to 6000 m/min). Aerodynamic processes are now widely used for drawing the filaments. They can be subdivided into primary, primary – tertiary, or tertiary air current processes depending on the relative locations of the spinnerets and the web-forming device. The air from the ambient surroundings used to cool the spun filaments is termed secondary air. A fourth process involves the combination of mechanical drawing over galettes with the subsequent aerodynamic process.

The choice of drawing and cooling systems affects the physical properties of the fibers (i.e., their crystallinity, strength, fineness, and shrinkage). The spun filaments are finally laid on a perforated, endless collecting belt with the help of mechanical or aerodynamical deflection devices. The resultant web is held on the belt by suction and conveyed to the bonding device. The random arrangement of the individual filaments is responsible for the isotropic physical properties of the end product which is an important quality feature of spunbondeds.

Du Pont Process. In the Du Pont process the filaments are bundled, drawn in air currents, and simultaneously cooled. Separate air currents may be used for cooling and drawing (with optional mechanical drawing) by means of drafting rolls. The fiber bundles can be deflected after striking a deflector, spread out, and sucked onto a perforated endless belt. Alternatively, they can be electrostatically charged in an aspirator; the individual filaments then repel one another and are deposited as a web on a grounded (earthed) conveyor belt (Fig. 12).

Two different polymers with different melting points can be spun from separate spinnerets. The filaments are jointly bundled, drawn, and laid to form a web. The lower melting point component acts as a binder fiber either immediately or when heated to a temperature above its melting point but below that of the higher melting component.

Figure 12. Schematic of the Du Pont spunbonded process
a) Spinning dies; b) Aspirator; c) Counterelectrode

Freudenberg Process. In the Freudenberg process (Fig. 13, see next page) the filaments are spun from rows of spinnerets fed from a spinning beam. The filaments are drawn in air currents in guide channels and laid under reduced pressure as a web on a suction belt. As in the Du Pont process, mixed webs can be produced with a lower melting point component that acts as a binder fiber.

Commercial Processes. In contrast to spunbonded processes developed by Du Pont, Freudenberg, and fiber manufacturers (e.g., Akzo, BASF, Hoechst, Rhône – Poulenc) whose spinning techniques have been developed only for their own use, companies such as Lurgi and Reifenhäuser market their processes and equipment worldwide.

The Lurgi – Docan process is based on the principle of tertiary air spinning and employs a rectangular-multifield die. The Reicofil process was introduced by Reifenhäuser in 1984 for the manufacture of polypropylene and polyethylene spunbondeds. The line uses an electri-

cally heated spinning head with a central melt line, the melt is distributed over the whole width according to the " clothes hanger system" used in flat-film production [48].

Figure 13. Schematic of the Carl Freudenberg process
a) Polymer melt; b) Air; c) Spinning beam; d) Spinning dies; e) Drawing channels; f) Drawn filaments; g) Web on transporting belt

Wet Spinning. In wet spinning the polymer (e.g., cellulose) is spun into a water bath where the fibers coagulate. The fibers are finally suspended on a suction belt (Asahi, Japan).

Flash spinning (evaporation spinning) developed by Du Pont has also become important. High-density polyethylene is dissolved in Freon or dichloromethane at elevated pressure and temperature in an autoclave to form a single-phase solution. This mixture is released from a nozzle into the atmosphere and expands. The low-boiling organic solvent vaporizes in an explosive manner (flash) and the polymer is scattered into a network of very fine filaments. Investment costs are roughly three times those for a wet line.

Exxon Melt-Blown Process. The melt-blown process developed by Exxon is a special spunbonded process. Molten polymer solution is forced at high pressure through dies (Fig. 14). On leaving the die the melt is entrained and drawn in the direction of the porous laying belt by a high-velocity hot air current. The incident forces must be sufficiently large to break off the fine fibers that are formed at the die exit. The fibers then pass through a current of cold air in which they solidify in their drawn form. They are deposited on the porous belt to form a web. Fibers with finenesses down to 1 µm can be spun as a result of process optimization and the development of special polymers with a high melt flow index (particularly polypropylene, polyester, polyethylene, and ethylene–vinyl acetate copolymer).

Figure 14. Melt-blown die
a) Hot air inlet; b) Heating plate; c) Capillary tube

Electrostatic Process [54, 55]. Extremely fine, electrostatically formed nonwovens are also classified as spunbondeds (Fig. 15). In order to manufacture extremely fine, bulky webs, a spray electrode is brought into contact with a polymer melt or solution. Charged polymer droplets are formed at the edge of the electrode and move with a threadlike deformation and possibly simultaneous evaporation of the solvent to a roller as counterelectrode. The resulting microfibers are continuously laid as a web (generally on a lightweight nonwoven carrier) and are covered on the upper side with a second lightweight nonwoven. The short deformed fibers in the web are electrostatically charged in

the high-voltage field; this improves the initial efficiency of filter materials.

Figure 15. Schematic of electrostatic web formation
a) Carrier material; b) Counterelectrode rolls; c) Covering layer; d) Spray electrode

Production Lines. Production lines for spunbondeds can be designed in widths exceeding 500 cm. In the lightweight web sector, continuous line speeds of up to 400 m/min have been achieved. The webs are bonded (1) by the inherent adhesion of the filaments during web formation, (2) by subsequent heating in thermofusion ovens without pressure, or (3) by application of pressure on smooth or embossed, heated calender rolls. The binders employed to bond dry-laid or wet-laid spun fiber webs can also be used to stabilize spunbondeds. Heavyweight spunbondeds are often compressed mechanically by needling.

High outputs are obtained under continuous operation with relatively high production rates. The long downtimes resulting from the complex cleaning process required in the wet process are avoided. Profitable production is only possible on a large scale, necessitating extensive markets with a high consumer demand. The process is not as flexibile as the dry and wet processes. However, in certain application areas spunbondeds are undisputedly superior to other textile fabrics on account of their economic and qualitative advantages (e.g., tuft backing, geotextiles).

3.2. Bonding of Nonwovens

In rare cases a fiber web can be used directly in the nonbonded state; for example in medical, cosmetic, or industrial waddings, which cohere as a result of the fiber friction produced by the crimp. However, by definition such products are not classified as nonwovens, they are fabrics made of fibers or filaments that have been subjected to a consolidating posttreatment.

3.2.1. Mechanical Bonding [56–68]

Wool or animal hair can be felted by felting and milling under the action of moisture, heat, pressure, and movement. The fibers interlock with one another and become entwined, with simultaneous consolidation (→ Felts).

Needle Punching. A nonfeltable fiber web can be consolidated by needle punching. The web is compressed by rollers and then punctured with a needle board during passage through one or more needle punching machines (→ Felts, Chap. 4.1.). The properties of the nonwoven are primarily determined by the fineness, cross section, number, and shape of the barbs on the needles, as well as by the number of needles (needle density), and penetration depth. The fibers caught by the barbs are bundled, simultaneously drawn into the web on entry of the needle, and become disengaged during the reverse movement of the needle. The web is then moved on a few millimeters and the procedure is repeated (typical rate 1000 – 2200 strokes per minute using 6000 needles per meter of working width). Speeds are 1 – 25 m/min and the working widths are up to 16 m. Bonding can be intensified by turning the web and passing it through the machine again or by needle punching both sides simultaneously. Structured surfaces with a velour character and patterns with a three-dimensional structure (pile nonwovens) can also be obtained with specially designed needles and needle punching machines.

The most important areas of application of needled nonwovens are carpet floor coverings, filter materials, supporting materials for coatings, household and domestic cloths, papermachine felt, velour leather imitates, and medical compresses.

Water Entanglement (Water-Jet Bonding). The so-called spunlace process developed by the U.S. companies Du Pont and Chicopee is a logical development of mechanical needling of webs. In contrast to needle punching, relatively lightweight (20 – 120 g/m^2) webs can be bonded by entanglement produced by water jets to form

nonwovens at high speeds (up to ca. 150 m/min). Although water entanglement is suitable for all types of web-forming processes based on a wide range of synthetic and natural fibers, it is primarily employed for bonding dry-laid nonwovens. Crimped polyester and viscose fibers with titers of 1.7 dtex and a length of 40 mm are mainly used. The fiber webs are prewetted on a perforated or patterned belt and then sprayed with water jets expelled from fine circular nozzles of 100–150 µm diameter at a pressure of 1.5–25 MPa (Fig. 16). The water jets strike the web and the fibers become intertwined and entangled at the points of impact. The degree of entanglement and thus the intensity of the bonding varies depending on the number of rows of jets, the water pressure, the size of the nozzle orifices, and the design of the carrier belt. The patterning of the carrier belt permits combined bonding and structuring of the nonwoven surfaces (e.g., to produce perforated nonwovens). The process is extremely energy-intensive on account of the high water pressures. Since the process water rapidly becomes contaminated with fiber fragments, it must constantly be subjected to multistage fine filtration. The resulting nonwovens have a soft textile hand, but their dimensional stability is poor; the latter can, however, be improved by posttreatment (e.g., additional chemical bonding).

Figure 16. Principle of the Valmet spunlace bonding process a) Jet manifold; b) Water jet; c) Nonwoven; d) Entangling substrate; e) Honeycomb shell; f) Vacuum seals; g) Vacuum box; h) Process water

The main areas of application are medical products (e.g., operating theater drapes and gowns, gauze substitutes), domestic textiles, and wiping cloths. Since additional capacity for this technology is being developed in Europe, Japan, and the United States, a range of new areas of application is anticipated. Manufacturers of water-jet bonding lines include Valmet (USA), Perfojet (France), and Unicharm (Japan).

Stitch Bonding. Stitch bonding, which includes the Maliwatt and the Maliweb processes, is also a form of mechanical bonding for nonwovens.

In *Maliwatt nonwovens* the web is bonded with a stitching thread that is drawn with a sliding needle through a previously formed stitch in the nonbonded web to form a new stitch. The old stitch is knocked over, resulting in warp-stitch seams, which in their simple form have a separable fringe weave, but in their locked form are no longer separable and therefore have a more stable knitted weave. The Maliwatt machine is manufactured in the former German Democratic Republic. The Arachne machine (equipped with closable tubular needles but otherwise of very similar construction) and its product Arabewa are manufactured in former Czechoslovakia. Depending on the stitch length, the working speed is ca. 1–4.5 m/min. Web weights of 100–500 g/m^2 can be processed on up to 560-cm wide lines. *Maliweb nonwovens* are also produced by stitch bonding but without perforated stitching-thread needles. During their return movement the sliding needles pick up small bundles of fibers that are formed into a stitch on the reverse side of the web. Production speeds are ca. 0.25–7.5 m/min, depending on the stitch length. The line width and web weights are similar to those quoted for the Maliwatt machine.

A thread reinforcement technique developed by the Karl Mayer and Liba companies (FRG) combines the special properties of nonwovens (e.g., softness and high bulk) with the high moduli of elasticity of threads. A row of warp threads is worked into the web to produce longitudinal reinforcement. Transverse or diagonal threads can also be laid and combined with the nonwo-

ven by interlocking with the length reinforcement. The properties of the end product depend on the number, orientation, and choice of thread material; stitch structure; and type of nonwoven.

Ultrasonic Bonding. This process was patented by Crompton and Knowles (USA) at the beginning of the 1970s. The mechanically produced vibration energy used to bond synthetic fibers (especially polypropylene) is generated in the frequency range 20 – 40 kHz. The width of the vibrating metal head (sonotrode) is only 200 – 250 mm. A number of sonotrodes therefore have to be arranged side by side in a calender. An unheated engraving roller of relatively small diameter serves as the anvil. There are few process parameters: the amplitude of the ultrasonic vibrations, the residence time of the web in the gap, the pressure load on the web, and the engraving geometry. The major advantage of the process is its substantially lower energy consumption compared to thermal bonding with calenders. It is used in particular with nonwovens having a weight greater than 100 g/m^2, e.g., in laminating processes (pinsonic process).

3.2.2. Adhesive Bonding [69–79]

The fibers in the web are usually bonded to one another with aqueous dispersions of adhesives (see Section 2.2). The binder content of the nonwoven is 20 – 60 wt %, generally between 20 and 30 wt %. The delicate, unstable web must be carefully handled during impregnation to avoid deformation.

Saturation. Two systems are conventionally used for saturation:

1) Impregnation between two screen belts (Fig. 17)
2) Impregnation between a screen belt and a screen roller (Fig. 18)

Flotation of the fibers and adherence to the screen belt may be a problem and require time-consuming cleaning. Accurate belt guidance is important, especially to ensure uniform suction when a suction device is used.

Impregnation in the Nip of a Padding Machine. This simple process (Fig. 19) can be used only with lightweight, readily wettable fiber webs. Application of the method is limited due to the short available distance for wetting the fiber that is determined by a fixed roller circumference and constant filling height of the trough.

Figure 19. Impregnation of lightweight, nonbonded webs in the nip of a padding machine
a) Web; b) Squeeze rolls; c) Impregnating liquid

Foam Impregnation in the Nip of Squeezing Rolls. In the C. L. Nottebohm process the web is coated on one side with binder foam

which is then allowed to dry. Complete impregnation is achieved by subsequent padding. In the method developed by Carl Freudenberg the loose web is passed directly to the nip of two squeezing rolls; the nip contains a foamed binder dispersion (Fig. 20).

Figure 20. Foam application in the nip of a squeezer
a) Distributor vat; b) Binder dispersion

The binder is distributed at the crossover points of the fibers, in contrast to saturation, in which the fibers are coated from all sides. Foam impregnation produces a textile drape, a soft handle, large bulk, higher air permeability, lower migration tendency, savings in binder and drying energy, and higher production rates. Attention must be paid to the consistency, wetting properties, and stability of the foam. Due to its numerous advantages, foam impregnation is one of the most popular adhesive bonding processes.

Spray Bonding. High-bulk webs are usually bonded by this technique. The webs pass through a chamber where they are sprayed with the binder dispersion from nozzles moving at right angles to the direction of movement of the webs. Oscillating sets of nozzles are used for mean production rates below 30 m/min. Rotating sets of jets have proved suitable for large working widths and/or high production speeds.

Uniform distribution of the sprayed droplets over the cross section of the fiber web is achieved by applying suction from below the web. Thicker webs are normally dried and then passed through a second spray station to bond the reverse side (Fig. 21). Each spraying operation is followed by a drying stage.

Figure 21. Spray bonding
a) Spray nozzle; b) Dryers; c) Rolling-up

Print Bonding. If the web is not to be bonded over its whole area but only partially in the form of a pattern or design, printing processes commonly used in the textile processing industry are employed (→ Textile Printing). In rotary printing a binder paste is forced with a doctor blade or roller bar through the perforations of the rotary screen onto the web. In relief printing the binder is transferred from the raised parts of a screen roller onto the web. Gravure printing and flexographic printing can also be used, but the web should then be prewetted or prebonded. Since the applied binders are generally colored, web bonding and dyeing can be performed in a single operation.

Drying and Cross-Linking. Binder-impregnated webs are converted into bonded nonwovens by drying and, if necessary, cross-linking and vulcanization. Air drying is generally preferred to contact drying on drying cylinders (can dryer). Infrared and high-frequency drying are rarely used.

In ventilation systems conventionally used in *air drying,* hot air is directed both parallel and perpendicular to both sides of the material. Single- and multi-tier dryers with air jets or parallel airstreams are preferred for relatively dense webs.

Air-through systems (suction drum dryer, Fig. 22) are preferred for the extremely intense drying of highly porous fabrics. Hot air flows inwards through the web. The drums operate under

reduced pressure. Honeycomb-type cylinders allow a higher vacuum and thus more efficient drying than conventional suction drum dryers. Air-through dryers can also be designed as band dryers with suction boxes arranged beneath the guide belt.

Figure 22. A honeycomb cylinder dryer
a) High vacuum suction; b) Vacuum suction; c) Air channel; d) Blow jet (to detach the web)

In *contact drying* with heated cylinders the impregnated web is dried and simultaneously smoothed in contact with the cylinder surface. Contact drying is only suitable for thin and relatively compact nonwovens.

Infrared radiation is used to coagulate heat-sensitive binders prior to drying to prevent binder migration. *High-frequency drying* also prevents migration, but has not been widely adopted on account of the high energy costs.

3.2.3. Thermal Bonding [80–93]

Thermal bonding of webs containing thermoplastic fibers is extremely important. Suitable fibers include those made of polypropylene, polyester and polyester copolymers, polyamide, modified poly(vinyl chloride), as well as sheath – core bicomponent fibers in which the low-melting component is utilized for bonding (see Section 2.1). Bonding with contact heat and pressure is the most important bonding method. In calender bonding (thermobonding) the web is bonded between two heated rolls with uniform pressure distribution over the machine width. In area bonding, pairs of steel – steel rolls as well as steel – coated rolls (e.g., with cotton or silicon) are used, depending on the weight and the required quality of the end product. In point bonding with engraved rolls, the engraving geometry is extremely important and affects the modulus of elasticity, softness, handle, and abrasion of the end product.

To obtain uniform line pressure, precise temperature control is required over the machine width; compensation of roll deflection in two-roll calenders is also very important in this respect. Calenders with deflection compensation rolls have been developed for temperatures up to 250 °C by Küsters (Hot-S-roll), Ramisch-Kleinewefers (Hydrein), and Escher Wyss/Freudenberg (Nipco).

In addition to calender bonding between two rolls, the Stork Beltbonder has achieved some importance, especially for producing powder-bonded nonwovens. Only a relatively low pressure can be achieved on the web to be bonded via the tension of the endless compression belt.

Thermal activation by means of hot air (thermofusion) is mainly used to manufacture high-bulk nonwovens. The air-through system is most suitable for this (see page 17) and has a continuously adjustable air flow, high temperature uniformity, and high heat-transfer coefficients.

The use of thermoplastic powders for bonding nonwovens had fallen into disuse, but is now enjoying renewed interest. Thermoplastic powders of copolyamides or copolyesters with melting points of 100 – 140 °C are uniformly incorporated into the fiber web and melted by heating with IR radiation or circulating air. The viscosity of the melted powder particles is low enough to ensure that web bonding occurs mainly at the fiber crossover points.

3.3. Finishing and Posttreatment [94–100]

Nonwovens can be finished in the same way as other textile fabrics, and to some extent also like paper or leather. Some treatments are, however, specific to nonwovens. Whenever the desired range of properties can be obtained by a suitable choice of raw materials, process materials, and manufacturing procedure, an attempt will always be made to avoid the finishing stage on grounds of cost.

Shrinking was introduced in the manufacture of nonwoven leather imitates to increase density and give the nonwoven a leatherlike handle. The needled web, containing 20 – 50 % of special, highly shrinkable fibers, is shrunk to ca. 50 % of its original area before further treatment in hot air, hot water, or steam.

Splitting of thick leather imitates into 2 – 6 plies is just as practicable as with natural leather. The same skiving machines with endlessly circulating band knives are used, with a gap accuracy of ± 0.05 mm.

Buffing with buffing machines conventionally used in the leather industry imparts a velourlike appearance to nonwovens.

Calendering as posttreatment (in contrast to calender bonding) can be used to impart a uniform thickness, for compaction, and to smoothen or emboss nonwovens. A more textilelike handle accompanied by loss in strength is obtained by partially destroying the binder adhesion.

Perforating and slitting result in drapable soft products. The water entanglement bonding process (see page 14) produces perforated structures directly. Needle or knife rolls can be used for perforation and notching of finished bonded nonwovens.

Compacting (Clupak process) and *crêping* (Micrex process) also serve to soften nonwovens. As in Sanforizing, the moist, generally adhesively bonded nonwoven is compacted in the longitudinal direction with structural compression between a compacted endless rubber belt and the smooth, steam-heated Clupak cylinder. In the Micrex process a dry nonwoven is compacted in the gap between a rotating grooved roller and a fixed guide plate; in contrast to the Clupak process a visible "crêping" effect can be obtained.

Dyeing is performed in adhesively bonded nonwovens with the application of the aqueous binder. Finely dispersed pigments in the binder liquor are usually sufficient. Binder-free, thermally bonded nonwovens can be produced from dyed fibers and can also be subsequently dyed either batchwise or continuously. Instead of being colored over its whole area, one or both sides of the nonwoven can be color printed.

Washing may be necessary to remove auxiliaries after dyeing and printing, to improve color-fastness, or to wash out surfactants and emulsifiers from nonwovens that are required to have a water-repellent finish. In household cloths and car cloths, washing removes pore-forming agents such as salts or urea. Full-width washing machines and suction drum washing machines are commonly used.

Coating of nonwovens is an important aspect of finishing. Area coating of nonwovens with poly(vinyl chloride) or polyurethane is commonly used in the shoe or leather imitate industry. Area coating with pressure-sensitive adhesives is also frequently used (e.g., in adhesive plaster substrates). Nonwovens coated with thermoplastic synthetic resins play an important role as fusible interlinings in the clothing and shoe industry. These dot-coated interlinings are bonded to the upper textile material or to leather under the action of heat and pressure. The interlinings impart form and shape to articles of clothing and are used in the ready-made garment industry. Compared to sewing or stitching, fusing (on steam presses, electric presses, and nowadays largely on continuous presses) has brought considerable cost advantages and a degree of standardization to ready-made garments. The proportion of fusing interlinings is about 80 – 85 % . The nonwovens are generally dot-coated with aqueous pastes or, occasionally, with anhydrous plastisols by rotary machine printing. The coating is dried in a hot air oven.

Preferred thermoplastic adhesives (hot melts) for fusing interlinings are copolyamides (e.g., of polyamide 6, 6.6, 11, or 12) or mixtures thereof with or without plasticizers. Copolyesters of widely varying monomer composition with melting points ranging from 100 to 140 °C are also important. Typical fusing conditions are a temperature of 100 – 150 °C for 4 – 12 s with minimum application of pressure. Under these conditions an optimum thermoplastic adhesive composition for the clothing industry results; this leads to the formation of an insoluble adhesion between the nonwoven and upper material that is resistant to repeated washing and dry cleaning.

On account of the temperature sensitivity of natural leather, the activation temperature of thermoplastic adhesives for shoe interlinings should not exceed 100 °C. Suitable adhesives include copolyesters, copolymers of vinyl chloride and vinyl acetate or of ethylene and vinyl acetate.

For simple fusing applications (e.g., in small parts of a garment such as waist bands) inexpen-

sive high-density polyethylene in powder form is scattered randomly onto the nonwoven substrate and sintered on.

An interlining nonwoven can also be spun-coated with a thermoplastic adhesive. Such spun webs can be extruded on release paper. After removal of the paper the spun nonwoven can be used for lamination processes. Nonwovens coated with thermoplastic adhesives have also been laminated by means of heat and pressure with membrane foils that are permeable to water vapor but impermeable to water and wind (e.g., Sympatex produced by Akzo, Goretex produced by Gore).

Dressing is often combined with nonwoven manufacture (e.g., by adding the agents to the binder liquor or, in the case of thermally bonded nonwovens, by a postfinishing treatment). Water-repelling agents (e.g., silicones and fluorocarbons), antistatic finishes, and flame retardants are applied in this way. Antibacterial, antimycotic, and fungicidal finishes can easily be applied with the binder liquor, or by postimpregnation in the case of thermally bonded nonwovens.

Heat setting is sometimes used to improve the dimensional stability (e.g., in interlinings). The nonwoven is exposed to hot air under controlled tension in a tenter frame dryer. The nonwoven material is transported through the heating zone of the tenter by holding both edges of the material at a predetermined width with tenter clips or needles.

The hot flue (a loop convection dryer) can also be used for thermal posttreatment. Like the suction drum dryer and tenter, the loop dryer is subdivided into several variable temperature zones, each zone can be traversed at a different speed.

These and other methods commonly used in textile processing can be applied to nonwovens.

4. Economic Aspects and Areas of Application

Economic Aspects. Industrial production of nonwovens (amounting to a few thousand square meters) began in the United States in 1944. After World War II nonwovens production experienced a sharp growth in all industrialized countries.

In 1987 ca. 30×10^9 m^2 of nonwovens were produced in the United States, Japan, and Western Europe. Annual growth rates up to 1987 were 10 %. Nonwovens production in the United States in 1987 was ca. 600 000 t, of which 150 000 t was spunbonded. In Japan production amounted to ca. 132 000 t, of which 30 000 t was spunbonded. Production for Western Europe (EDANA) was 342 000 t, spunbondeds accounting for 111 000 t.

Lightweight nonwovens below 25 g/m^2 (mainly used for diaper top sheets) account for slightly more than one-third of production. Nonwovens weighing between 25 and 70 g/m^2 account for almost a quarter, and nonwovens from 70 to 150 g/m^2 and above account for the remainder.

Areas of Application. Tables 3, 4, 5 summarize the production and use of nonwovens in Western Europe, the United States, and Japan, according to their main areas of application.

Table 3. Nonwovens production (in 10^3 t) in Western Europe according to areas of application (based on data supplied by EDANA)

5. Testing [101–104]

Nonwovens are tested in accordance with national and international standards.

Federal Republic of Germany

DIN 53 482-79E	Electrical resistance
DIN 53 854	Weight determinations (1975)
DIN 53 855 1 + 2	Determination of the thickness of textile fabrics (1982)
DIN 53 857, T-2-79	Simple strip tensile test
DIN 53 859, T1, 2, 5-77/84	Determination of needle tear resistance
DIN 53 887	Determination of air permeability
DIN 53 890	Determination of crease recovery angle (1979)
DIN 53 878	Determination of dimensional change in textile fabrics (1987)
DIN 54 303 T1, 2-88	Behavior of nonwovens during dry cleaning
DIN 54 304 T1-88	Behavior of nonwovens during washing
DIN 54 305-76	Determination of the compression elasticity behavior
DIN 54 307	Indentation test (1982)
DIN 54 310	Separation of fixed interlining from upper material (1980)
DIN 54 311	Determination of dimensional change in fixed interlinings
DIN 61210 T1, 2-1987	Draft, definition and determination of nonwovens

International Standards Organization

ISO 9073-1	Determination of mass per unit area of nonwovens
ISO 9073-2	Dermination of thickness of nonwovens
ISO 9073-3	Determination of tensile strength and elongation of nonwovens
ISO 9073-4	Determination of tear resistance of nonwovens
ISO 9092	Textiles – nonwovens definition

European Disposables and Nonwovens Association

101-72	Determination of the liquid uptake capacity
201-73	Tensile strength testing
303-78	Determination of thickness
402-77	Determination of weight
502-80	Determination of bending length (cantilever)
601-75	Adjustment to standard climatic conditions
701-75	Determination of tear growth resistance
801-75	Determination of bursting pressure
901-76	Determination of drapeability
1001-78	Determination of brightness (brightness/degree of reflection in the blue part of the visible spectrum)
1101-78	Determination of opacity
1201-80	Water pressure test (water tightness)
1301-80	Sampling
150-0-84	Liquid penetration time through nonwovens
160-0-84	Surface “linting”
1401-81	Air permeability

United States

ASTM D 1117-80	Section
Abrasion resistance	18
Absorbency time and absorptive capacity	5
Air permeability	6
Breaking load and elongation of fabrics	7
Bursting strength	8
Conditioning	4
Dimensional change	9
Dry cleaning	10
Flexural rigidity	11
Recovery from creasing	12
Seam breaking strength	13
Tearing strength of fabrics	14
Trapezoid tear	14
Tongue tear	15
Elmendorf tear	16
Thickness	19
Weight	17

Abbreviations and symbols used in this article

Abbreviations for reactors

AGR	advanced gas-cooled reactor
ATR	advanced thermal reactor
AVR	Arbeitsgemeinschaft Versuchsreaktor
BWR	boiling-water reactor
CANDU	Canadian heavy-water-cooled pressure tube reactor
EFR	European fast reactor
FBR	fast breeder reactor
GGR	gas-cooled graphite-moderated reactor
HTR	high-temperature reactor
HWR	heavy-water reactor
LMFBR	liquid metal fast breeder reactor
LWGR	graphite-moderated light-water-cooled reactor
LWR	light-water reactor
MZFR	Mehrzweck-Forschungsreaktor (multipurpose research reactor)
PHWR	pressurized vessel heavy-water reactor
PWR	pressurized-water reactor
SGHWR	steam-generating heavy-water reactor
SPX	Superphénix
THTR	thorium high-temperature reactor

Further abbreviations

AECL	Atomic Energy of Canada Limited
AISI	American Iron and Steel Institute
ALARA	as low as reasonably achievable
ASME	American Society of Mechanical Engineers
AVT	all volatile treatment
BNFL	British Nuclear Fuel
BR	conversion or breeding rate
COGEMA	Compagnie Générale des Matières Nucléaires
CRDM	control rod drive mechanism
CRT	cathode ray tube
DNB	departure from nucleate boiling
EAR-I	estimated additional resources, cat I
EAR-II	estimated additional resources, cat II
ECL	extra low carbon steel
ECP	electrochemical potential
FIFA	fissions per initial fissile atoms
FIMA	fissions per initial (heavy) metal atoms
hm	heavy metal
HAW	high active waste
HEU	highly enriched uranium and thorium
IAEA	International Atomic Energy Agency
ICF	inertial confinement fusion
ICRP	International Commission on Radiological Protection
IHX	intermediate heat exchanger
I&C	instrumentation and control
ISR	Institut für Sicherheitsforschung und Reaktortechnik
IUREP	international uranium resources evaluation project
KTA	Kerntechnischer Ausschuß
LAW	low active waste
LEU	low-enriched uranium
LPRM	local power range monitoring system
MAW	medium active waste
MCA	maximum credible accident
MOX	mixed oxide
PCRV	prestressed concrete reactor vessel
PUREX	plutonium, uranium, reduction, extraction
RAR	reasonably assured resources
RCC-M	Règles de Conception et de Construction, Part "Mechanical components of PWR nuclear islands"
RHR	residual heat removal
RPV	reactor pressure vessel
SR	speculative resources
StrlSchV	Strahlenschutz-Verordnung
TIG	tungsten-inert gas
WOCA	world outside centrally-planned economic areas

Symbols

A	mass ratio of nucleus to neutron
B	burnup
d_{q}	phase-space element
D	energy dose, distribution coefficient
$\dot{D}$	energy dose rate
D	extent of damage
D_{h}	hydraulic cooling channel diameter
D_{q}	dose equivalent
$\dot{D}_{\mathrm{q}}$	equivalent dose rate
DF	decontamination factor
E	modulus of elasticity
F_{Q}	form factor
f	plant utilization
I	ion dose
k_{eff}	neutron multiplication factor
k_{F}	specific fuel cost
k_{p}	specific cost of the plant
K	activity concentration
L	leakage rate
M_{F}	fuel mass
N	particle concentration
n	neutron density
p_{st}	steam pressure
P_{D}	probability of damage
P_{e}	electrical output
P_{p}	pump or blower power
P_{th}	thermal output
q	quality factor
q'	specific fuel rod power
q''	heat flux density
q'''	power density
q'''_{max}	permissible power density
q_{sp}	average specific power
r	radius
R	reaction rate
R_{D}	risk of damage
T_{c}	coolant warming up span in the reactor
T_{o}	maximum (central) fuel power
T_{st}	steam temperature
V_{c}	flow rate of the coolant
x	distance
α	heat transfer coefficient
β	fraction of delayed neutrons
δ	ultimate elongation
ε_{a}	macroscopic efficient thermal neutron cross-section
η	thermal efficiency factor
η_{c}	viscosity of the coolant
λ	mean free path
λ_{D}	radioactive disintegration constant
λ_{C}	thermal conductivity
ν	neutron velocity
ξ	logarithmic mean energy loss
Ω	solid angle
ϱ_{c}	density of the coolant
Σ_{f}	macroscopic fission cross-section
σ	cross-section; strength values
τ	half-life
Φ	neutron flux density, neutron flux
χ	energy per fission

1. Fundamentals

1.1. Introduction

Early in 1939, Otto Hahn and Fritz Strassmann published their discovery of nuclear fission in the uranium isotope ^{235}U [1]. Their disclosure marked the beginning of nuclear technology [2], whose goal is to utilize the energy liberated in this process.

The fission of an atomic nucleus is caused by penetration of a neutron into the nucleus, which splits into two fission products (i.e., nuclei of lighter atoms). In addition, the fission releases two to three neutrons, on average, along with γ radiation. The kinetic energy of the fission products and neutrons is imparted to the surrounding matter by collisions and – together with the absorbed radiation – heats it. An energy of some 200 MeV (i.e., 3.2×10^{-11} J) is produced in each fission, whereas in conventional energy generation, the formation of a molecule of carbon dioxide liberates about 4.2 eV (i.e., 6.7×10^{-19} J).

For nonfissionable nuclides, addition of a neutron to the nucleus leads to the formation of an isotope with a higher neutron number. In this way, new nuclides – in particular, the fissile materials ^{233}U, ^{239}Pu, and ^{241}Pu – can be artificially "bred."

Utilization of these physical processes occurs in nuclear reactors. Contained in fuel elements, the fission and breeding processes take the form of a chain reaction, which is continuously sustained by the neutrons generated. The heat liberated is used to produce electrical power, and the fissile breeding products serve to extend the operating cycle.

Most nuclides created in nuclear processes are unstable and decay by emitting radioactive radiation. Therefore, reliable means must be provided to keep them out of the biosphere. Nuclear

reactors include highly advanced safety systems, which ensure the containment of radioactive materials in all normal and accident situations. In the same way, the transport of spent fuel assemblies from the reactor, their processing, and the storage of the radioactive waste must all occur under conditions of reliable isolation.

The use of nuclear energy for *power generation* was demonstrated in 1951, when a small reactor at Oak Ridge produced 150 W of electrical power. The first central power station reactor producing 90 MW_e began commercial operation at the end of 1957 in the United States. By 1988, the nuclear industry's contribution to worldwide power output had risen to 17 %; in France, a special case, the nuclear share was 70 %.

The use of nuclear energy is not limited to electrical power. Reactors are used to propel ships [3], especially submarines and icebreakers [4]. The possibility of creating new fissionable nuclides has led to the development of breeder reactors, in which an excess of fissile material can be recovered [5–7]. High-temperature gas- cooled reactors, which heat their coolant to 950 °C, represent a new energy source for chemical processes in the field of high temperature, and for the synthesis of liquid fuels [8–10]. Heat reactors are being devised to supply district heating networks in both large cities and small communities [11], [12]. When located close to these heat consumers, the reactors must be equipped with advanced safety features, and, beyond that, must be fully accepted by the population.

Development work at present is concentrated on reactors employing much-simplified technology for dealing with accidents. Smaller reactor units, up to 600 MW of thermal power, can be designed to stabilize themselves naturally after destabilization, with no possibility of radioactivity escaping [13], [14]. Larger power plants can be assembled from such smaller reactors in modular fashion.

Energy demand worldwide is expected to increase substantially. The consumption of fossil fuels must, however, be limited on ecological grounds. These constraints make it desirable to satisfy the increasing demand for energy through the utilization and further development of nuclear power.

1.2. Design of a Nuclear Reactor

Nuclear power plants use the heat liberated by fission processes for steam generation. The steam drives a turbine generator, which produces electricity. In contrast to power plants using fossil fuels, the heat generation process must be strictly isolated from the environment.

The components essential for the operation and safety of nuclear reactors are illustrated in Figure 1 for a pressurized-water reactor [15–17]. The reactor core is made up of a number of *fuel assemblies*. They consist of an array of fuel rods, which are metallic tubes filled with a stack of uranium dioxide (UO_2) fuel pellets. Here, the heat-producing nuclear processes occur. Cooling water under a pressure of 16.0 MPa flows around the fuel rods and carries the heat to the steam generator.

Figure 1. Schematic diagram of a pressurized-water reactor a) Reactor core; b) Reflector; c) Pressure vessel; d) Control rods; e) Main coolant pipe; f) Main coolant pump; g) Steam generator; h) Piping to turbine; i) Decay power removal system; j) Accumulator (borated water); k) Safety vessel; l) Reinforced-concrete containment

The water simultaneously functions as a *moderator*. Neutrons are slowed (moderated) by elastic collisions with nuclei of the water molecules, thus coming to thermal equilibrium with the scattering nuclei (see Section 1.3.5). Outside the reactor core, water serves as a *reflector*, deflecting part of the escaping neutrons back into the core by scattering processes.

To regulate or terminate the chain reaction, *control rods* are moved between the fuel rods. The control rods contain a strong absorber of neutrons, for example, boron. In addition, neutron-absorbing boric acid can be injected into the water.

When the reactor is shut down, heat production in the fuel rods does not stop completely. Decay power output results from the decay of unstable nuclides, especially fission products. To prevent overheating of the fuel rods, a separate cooling system is installed for removal of the decay power. The reactor equipment includes several independent water supply systems, which ensure that the fuel assemblies will remain covered with water and cooled during accidents.

The reactor and its components are surrounded by steel shell containment and a reinforced-concrete containment building in which a slightly subatmospheric pressure is maintained. These structures form an external barrier against the escape of radioactive nuclides during operation or in the case of accident. At the same time, they afford protection against outside events, such as the impact of an aircraft.

The components named relate to the operation and safety of the reactor. They are also present, although in modified form, in other reactor types that have come into use (Table 1).

Modular Reactor Design. The purpose of developing small modular reactors is to simplify engineering design. In these reactors, active measures for ensuring the safety of the reactor in accidents are replaced by passive measures.

In *modular liquid-cooled reactors*, the entire primary coolant circuit including the heat exchanger is located inside the reactor pressure vessel. A containment vessel surrounds the pressure vessel closely enough for the fuel assemblies to remain covered by coolant, even in the event of a leak. Emergency coolant injection is thus superfluous, and decay power is carried away by natural circulation.

In *modular high-temperature reactors*, decay power is absorbed in the graphite of the fuel elements, carried to the pressure vessel wall by radiation and conduction, and from there removed to the surroundings. In this way the temperature of the fuel elements is limited and does not reach a region where fission products can diffuse through the fuel cladding. Even in accidents involving loss of coolant from the reactor, the fission products remain confined in the fuel elements.

1.3. Physical Processes [18–26]

Reactor operation involves closely associated processes of neutron physics, burnup, heat transfer, and fuel handling. For an existing reactor, these steps are monitored and measured. In contrast, facility design, construction, and licensing of a reactor are based on computer simulations that build up the history from repeated calculations of the many partial processes involved. The simulation also offers insight into physical processes that are not accessible for experimental study.

1.3.1. Structure of Atomic Nuclei

The atomic nucleus is made up of about equal numbers of protons and neutrons (both included in the term "nucleons"). Heavy nuclei contain more neutrons than protons. Neutrons and protons are held together by nuclear forces. The analogy with a drop of water led Gamow [27] to introduce the " liquid drop model," which describes the increase in nuclear volume and, approximately, the increase in nuclear binding energy with nucleon number.

Five types of internal forces are distinguished: (1) an extremely short-range (2×10^{-13} cm) attractive term; (2) a term considering the assymmetric distribution of forces at the surface, analogous to surface tension; (3) repulsive forces attributed to Coulombic interaction between protons; (4) weakening of bonds due to unequal proton and neutron numbers; and (5) saturation of nucleon spin states. The binding energy of a nucleon in the nucleus is approximately 8 MeV.

1.3.2. Reactions with Neutrons [28]

The liquid drop model offers an easy way to visualize nuclear fission. The entry of a neutron

Table 1. Reactor types

Type	Abbreviation	Fuel	Moderator	Coolant	Refueling	Burnup, MW · d/kg
Pressurized-water reactor	PWR	LEU [a]	H_2O	H_2O	annual	36

[a] LEU = low enriched uranium.
[b] U_{nat} = natural uranium containing 0.711 % ^{235}U.
[c] HEU = highly enriched uranium and thorium.

adds energy to the nucleus, which becomes deformed and executes surface vibrations (Fig. 2). If the excitation energy is greater than a threshold value, the Coulombic repulsion exceeds the restoring surface tension, and the nucleus splits. If the threshold energy is not reached, the capture of a neutron leads to the formation of the next higher nuclide and the emission of γ radiation [an "(n, γ) process"] (see Tables 2 and 3).

Table 2. Energy release, in MeV, on fission of ^{235}U

Kinetic energy of fission products	169.6
Kinetic energy of fission neutrons	4.8
Prompt γ radiation	7.0
γ Radiation from decay of fission products	6.3
β Radiation from decay of fission products	6.4
Neutrinos	8.7

Figure 2. Nuclear fission in the liquid drop model

If a nucleus with an odd number of neutrons captures a neutron, pair saturation of the neutron spin occurs, resulting in a slight additional increase in excitation energy. This is why odd-neutron nuclides (e.g., ^{233}U, ^{235}U, ^{239}Pu, ^{241}Pu, so-called fissile materials) undergo *fission* upon the addition of neutrons with low kinetic energy (i.e., thermal neutrons). Even-neutron nuclides, such as ^{232}Th and ^{238}U (so-called fissionable materials), mainly exhibit *neutron capture* and are likely to undergo fission only in the case of high-energy (fast) neutrons.

Along with fission and capture, *collision processes* are important. The slowing-down of neutrons by the nuclei of the moderator (H_2O, D_2O, C, Be) involves *elastic scattering*, in which the neutron is again free after its capture and the nucleus remains unexcited. In *inelastic scattering*, the neutron escapes after the collision but leaves the nucleus in an excited state, which decays by the emission of γ quanta. In *inelastic collisions*, a fast neutron knocks one or two additional neutrons out of the nucleus [(n, n′) and (n, 2 n) reactions]. In certain nuclides, high-energy gamma quanta can induce the emission of a neutron [(γ, n) processes].

1.3.3. Decay

A nuclear reaction leaves the nucleus in an unstable state, which decays with a certain half-life.

The fission product nuclei (daughter nuclides) generated in a nuclear fission process have a high excitation energy. In some cases, in a process with a half-life between 0.2 and 55 s, the daughter nuclide emits a *neutron* and changes to the nuclide with the next lower neutron number. These "delayed" neutrons represent only a fraction of about 0.2 – 0.7 %, compared to the neutrons emitted "promptly" upon fission, but the delay makes a significant contribution to stabilizing the chain reaction (see Section 1.3.7).

In α *decay*, a helium nucleus is emitted. The proton and neutron numbers are each reduced

Table 3. Nuclear fission process

Property of the nuclides	^{233}U	^{235}U	^{239}Pu	^{241}Pu	^{232}Th ∗	^{238}U ∗

A) In breeding; B) Isobaric fission products with atomic mass 135 (yield = nuclei produced per 100 fissions in ^{235}U)

by two. Alpha radiation is strongly ionizing but it has a short range.

An internal neutron – proton transformation is involved in β *decay*. The β emitters are classified as β^- (electron) and β^+ (positron) emitters.

γ *Emission* represents high-energy electromagnetic radiation in the 1-MeV region. Because of its long range, γ radiation requires thick shielding.

Decays often occur in succession until a stable state is reached. One such chain begins with the capture of a neutron by ^{238}U and ends in the formation of the fissile nuclide ^{239}Pu (Fig. 3). Most fission products decay in a similar way until stable nuclides are formed. Because of their radiotoxic properties, active reactor materials must be kept shielded and isolated from the biosphere.

1.3.4. Cross-Sections

The probability that a neutron approaching a nucleus will react with it is expressed in terms of the cross-section σ. The cross-section of a nucleus represents the area, normal to the direction of the incident neutron, that the neutron must hit to react with the nucleus. The larger the cross-section, the higher is the probability of a neutron – nucleus reaction.

Cross-sections have the dimensions of area and the unit barn: 1 barn = 10^{-24} cm^2. The cross-section depends strongly on the energy of the incident neutron and often exhibits selective maxima that correspond to resonance absorption or scattering at certain neutron energies (analogous to light absorption by atomic electron shells; see Figs. 4 and 5 [29]). The reaction cross-section may exceed the geometric cross-section of the nucleus by a factor of more than 10^6.

Cross-sections are identified by the nuclear reaction in question: σ_f for fission processes, σ_c for neutron capture, σ_s for scattering. The absorption cross-section is $\sigma_a = \sigma_f + \sigma_c$, and the total cross-section is $\sigma_t = \sigma_a + \sigma_s$.

In a medium with N nuclei per cubic centimeter, the product

$$N \cdot \sigma = \Sigma$$

is the macroscopic cross-section. This equation applies to each of the various nuclides and their reactions and also to their sum. In what follows,

Figure 4. Microscopic cross-sections for ^{235}U at 1273 K
—— σ_f; $\cdots$ $\sigma_a = \sigma_f + \sigma_c$

Figure 5. Absorption cross-section σ_a of ^{238}U in the resonance region (1273 K)

Σ is used without identifying information; for example, $\Sigma_f(^{235}U) \rightarrow \Sigma$. The probability that a neutron will travel a distance x without reacting is given by $e^{-\Sigma x}$. The quantity

$$\frac{1}{\Sigma} = L$$

is the mean free path. Its typical value is a few centimeters; near a strong resonance, it will be a fraction of a millimeter.

Absorption resonances are particularly marked in the case of ^{238}U. The energy region between 4 and 4000 eV contains 416 resonances. Out of a continuous neutron energy spectrum, the neutrons with energies near the resonances are selectively absorbed (Fig. 6). The fraction of such neutrons is increased by the thermal motion of the nuclei: since the nuclei move with and against the direction of neutron flight, neutrons whose actual kinetic energies lie outside the natural width of a resonance are also absorbed. This phenomenon is analogous to the Doppler effect as known in optics and acoustics. For computational purposes, the effect is described in terms of temperature-dependent broadening of the resonances [30].

The temperature-dependent resonance absorption of ^{238}U is very important for nuclear reactor control. In normal operation, this effect stabilizes the chain reaction. In accidents where the fuel is heated, the enhanced neutron absorption causes the chain reaction to decay because

of insufficient heat removal. This mode of reactor control through the fuel temperature is independent of the operability of reactor equipment. It is an inherent property of the reactor, because it is based solely on natural laws.

1.3.5. Moderation of Neutrons

Nuclear fission produces neutrons with energies between 0.1 and 10 MeV. These are slowed by elastic collisions with light moderator nuclei (e.g., H_2O, D_2O, C) until they reach thermal equilibrium with them (see Table 4). In the thermal energy range, the neutrons experience ca. 30 – 200 collisions before they are captured or initiate a fission. The residence time at thermal energies is ca. 10^{-3} s, which is the major part of the generation time of a neutron.

The energy given up by a neutron in a collision is determined under a rigid-sphere model. The energy loss is a maximum in a central collision; if the starting energy is E_1, it leads to the energy:

$$E_2 = E_1 \left(\frac{A-1}{A+1}\right)^2$$

where A is the mass ratio of nucleus to neutron. When colliding with a hydrogen nucleus ($A = 1$), a neutron can give up all of its energy in a single collision; this is not possible with heavier nuclei. On the average, the energy E_2 after collision is a constant fraction of the neutron energy E_1 before collision. The logarithmic mean energy loss per collision $\xi = \ln(E_1/E_2)$ is:

$$\xi = 1 + \frac{\alpha}{1-\alpha}\ln\alpha \quad \text{where} \quad \alpha = \left(\frac{A-1}{A+1}\right)^2$$

The logarithmic mean energy loss is a constant for each moderator material.

If no light moderator nuclei are available, the neutrons are moderated in smaller steps. In the fast breeder reactor (FBR), for example, neutrons are scattered on ^{23}Na nuclei. Most of the neutron absorption and fission events in this reactor take place at fast neutron energies. This fact is the reason the FBR is referred to as a "fast" reactor. In "thermal" reactors, on the other hand, fission is mainly initiated by neutrons that have reached the energy range of thermal equilibrium.

—— 0 K; · · · · 1273 K

1.3.6. Neutron Flux [31–33]

The distribution of neutrons in the reactor is characterized by the neutron density n. The product of neutron density and velocity ν is the neutron flux density ϕ, usually called "neutron flux"

$$\phi = \nu \cdot n \tag{1}$$

This quantity tells how many neutrons per second pass through a surface element of unit area in all directions. It is equal in magnitude to the sum of the distances traveled by all neutrons from a unit volume in a second.

The ratio of this distance ϕ to the mean free path Λ of neutrons in a given medium

$$R = \frac{\phi}{\Lambda} = \Sigma \cdot \phi$$

is the number of reactions per second in the unit volume, that is, the reaction rate R. Reaction rates can be determined separately for various types of nuclear processes, for various materials present in a reactor, and for various positions in space. Determination of reaction rates is a central problem in reactor physics. The macroscopic cross-sections Σ required for this purpose characterize the properties of the materials and their spatial distribution in the reactor; their values are thus set by reactor design. The neutron flux

Table 4. Number of collisions with moderator nuclei ∗

Range of collision	Energy	LWR	HTR	FBR
Thermalization of fast neutrons	2 MeV → 1 eV	16	92	171
In region of ^{238}U resonances	4000 → 4 eV	8	44	82
At thermal energy	$E < 2$ eV	50	200	

∗ LWR = light-water reactor; HTR = high-temperature reactor; FBR = fast breeder reactor.

ϕ describes the distribution of neutrons that can initiate reactions, and this quantity must be determined by computation.

Calculation of Neutron Flux. Neutron flux can be calculated in two ways. The principal way is to write a *balance equation* for the neutron density and solve it numerically. Another method is based on *direct calculation of the fate of individual neutrons* in the real reactor configuration. The point of origin of the neutron is selected on the basis of a statistically generated random number. Analogously, random numbers are applied to select the direction of flight, its energy within the fission spectrum, and all other quantities having the sense of probabilities. In this way, a flight path can be determined for the neutron from birth through the many scattering processes to absorption. When a great number of individual histories have been simulated by a computer, the distribution of the neutron flux is found by averaging. The procedure is called the "Monte Carlo" technique; when detailed information is given on the geometric configuration of the reactor, it can yield very reliable results.

The *balance equation* for the neutron flux is formulated in a similar way to the balance equation for the number of gas molecules per unit volume, as introduced by BOLTZMANN in the kinetic theory of gases. In a detailed treatment, the neutron density, the flux, and the reaction rate are functions of position, velocity, and time. The expression

$$n\left(\vec{r}, E, \vec{\Omega}, t\right) \mathrm{d}V \, \mathrm{d}E \, \mathrm{d}\vec{\Omega}$$

gives the number of neutrons located in the volume element dV at position $\vec{r}$ at time t, having kinetic energy between E and $E + \mathrm{d}E$, and moving in a direction lying in the solid-angle element $\mathrm{d}\vec{\Omega}$ at solid angle $\vec{\Omega}$.

These variables represent coordinates in phase space. The reaction rate

$$R\left(\vec{r}, E, \vec{\Omega}, t\right) \mathrm{d}q = \Sigma\left(\vec{r}, E\right) \cdot \phi\left(\vec{r}, E, \vec{\Omega}, t\right) \mathrm{d}q$$

is the number of reactions per second in the phase-space element $\mathrm{d}q = \mathrm{d}V \, \mathrm{d}E \, \mathrm{d}\vec{\Omega}$.

By analogy with the kinetic theory of gases, the Boltzmann equation for neutron flux is derived from the balance equation for reaction rates. In terms of neutron flux it is given as:

$$\frac{1}{\nu} \frac{\partial \phi\left(\vec{r}, E, \vec{\Omega}, t\right)}{\partial t} \mathrm{d}q = \text{Gains} - \text{Losses} \qquad (2)$$

using the definition of ϕ in Equation (1). Losses include all reaction rates that lead out of the phase-space element dq: absorption, scattering into other phase-space elements, and neutrons moving out of the spatial volume element dV. Gains are in-scattering events from other phase-space elements, newly produced prompt fission neutrons, and delayed neutrons.

For a real reactor, because of its complex structure, this equation cannot be solved numerically. The problem is, therefore, simplified and subdivided in various ways. Normally, integral quantities are formed, and the balance equation is transformed to a balance equation for these quantities. For example,

$$\phi\left(\vec{r}, E, t\right) = \int_{\vec{\Omega}} \phi\left(\vec{r}, E, \vec{\Omega}, t\right) \mathrm{d}\vec{\Omega}$$

represents the neutron flux integrated over all directions of flight. For the energy dependence, an expansion in integral values over wide subintervals or "energy groups" ΔE_{g} is usual:

$$\phi_{\mathrm{g}}\left(\vec{r}, t\right) = \int_{E_{\mathrm{g}}}^{E_{\mathrm{g}} + \Delta E_{\mathrm{g}}} \phi\left(\vec{r}, E, t\right) \mathrm{d}E$$

The position dependence can also be represented by integral values over subregions J formed by volumes ΔV_J.

Most commonly, the quantity of interest is the neutron flux when the reactor state is constant over time. In this case, the problem can be simplified to solving the steady-state equation $\partial\phi/\partial t = 0$.

In practice, the calculation is often performed in two steps. First, a representative cell is formed for each of various local subregions of the reactor. The cell represents the geometry of a fuel rod and the surrounding material. The neutron flux $\phi\left(\vec{r}, E\right)$ is calculated for each cell, and this flux function is used in forming an average for the cross-sections of the various materials located within the cell. These are found by integrating the reaction rates to

$$\sigma_{\mathrm{J,g}} = \frac{\int\limits_{\Delta V_{\mathrm{J}}} \mathrm{d}V \int\limits_{\Delta E_{\mathrm{g}}} \mathrm{d}E \cdot \sigma\left(\vec{r}, E\right) \cdot \phi\left(\vec{r}, E\right)}{\int\limits_{\Delta V_{\mathrm{J}}} \mathrm{d}V \int\limits_{\Delta E_{\mathrm{g}}} \mathrm{d}E \cdot \phi\left(\vec{r}, E\right)} \quad (3)$$

where the denominator is the integrated neutron flux.

Second, the averaged cross-sections of the subregion J are assigned to the respective positions $\vec{R}$ in the reactor $[\sigma_{\mathrm{J,g}} \rightarrow \sigma_{\mathrm{g}}(\vec{R})]$ and used for calculating the global distribution of the neutron flux. Under some simplifying assumptions, Equation (2) takes the form of a diffusion equation, whose solution gives the neutron-flux distribution $\phi_{\mathrm{g}}(\vec{R})$ by energy groups g and over the entire reactor volume. The integral neutron flux is

$$\phi = \sum_{\text{groups g}} \int\limits_{\text{reactor}} \phi_{\mathrm{g}}\left(\vec{R}\right) \cdot \mathrm{d}V \quad (4)$$

This flux is normalized such that the integral fission rate R_{f} formed with it (see Section 1.3.8) equals the power output of the reactor. In real reactor operation, this corresponds to adjusting the neutron flux with control devices to obtain the desired heat output.

At thermal energies, the neutron-flux function is determined by scattering on moderator nuclei. The thermal motion of these nuclei influences the neutron spectrum (Fig. 7), and for this reason the mean cross-sections from Equation (3) depend on the moderator temperature (Table 5). Like the Doppler effect in resonance absorption, this temperature dependence is an inherent property that contributes to automatic control of the reactor. However, the averaged cross-sections for both neutron capture $\sigma_{\mathrm{c,J,g}}$ and fission $\sigma_{\mathrm{f,J,g}}$, (i.e., the rate of neutron loss and the rate of new neutron production) are also temperature dependent. In some reactor concepts, the increase in fission rate with increasing temperature is dominant [34]; these reactors have a positive moderator temperature coefficient. In most reactors, enhanced neutron capture is the dominant effect, and an increase in temperature results in automatic shutdown.

Table 5. Mean thermal absorption cross-sections $\sigma_{\mathrm{a,J,g}}$, barn (averaged with neutron flux in light-water reactor fuel assembly from Fig. 7).

1.3.7. Time Dependence of Neutron Flux [35], [36]

Reactor control actions and accidental situations cause a change in neutron flux over time. In computational terms, this process is described by solving the time-dependent balance equation (Eq. 2) or the corresponding time-dependent diffusion equation.

With regard to time, the neutron gain due to fissions must be divided into a prompt and a delayed fraction, as described in Section 1.3.3. The fraction of prompt neutrons is between 99.3 and

99.8 %, and their generation time is ca. 10^{-3} s. The delayed neutrons, with a fraction of 0.2 – 0.7 %, have a mean generation time of around 13 s (Table 6). It is also important that the neutron loss at the absorption resonances increases with increasing temperature (Section 1.3.4).

Table 6. Delayed neutrons in six decay groups ∗

Group	^{235}U		^{239}Pu	
i	τ_i, s	β_i, %	τ_i, s	β_i, %
1	0.18	0.018	0.22	0.008
2	0.50	0.088	0.55	0.023
3	2.23	0.281	2.09	0.074
4	5.98	0.130	5.17	0.049
5	21.84	0.140	22.29	0.063
6	54.49	0.026	53.73	0.009
Total β		0.690		0.226
Mean τ	8.81		9.53	

∗ τ = half-life, β = fraction per fission neutron.

In normal reactor operation, the neutron flux is at equilibrium and $\partial\phi/\partial t = 0$. This state is perturbed by a change in neutron losses, for example, when the control rods are moved or the coolant flow rate varies. According to Equation (2), a reduction in neutron losses brings about an increase in the neutron flux over time, $\partial\phi/\partial t > 0$. As a consequence, the neutron gain increases in the subsequent neutron generation, because the rate of production is proportional to the flux. The incremental increase is very different for the prompt and delayed neutrons because of their different generation times.

If the decrease in losses is *high*, the increase in flux is governed by the generation time of the prompt neutrons. The flux increases by orders of magnitude in a fraction of a second. This condition is called "prompt criticality"; it cannot be controlled by technical measures. However, at the same time, any increase in flux is associated with an increase in reactor output, that is, heat production in the fuel assemblies. If the temperature increases by 100 °C, neutron absorption increases by 0.2 – 0.8 %, depending on the reactor type; in this way an excursion can be controlled by the rise in fuel-assembly temperature.

However, if the decrease in neutron losses is *low*, i.e., less than the fraction β of delayed neutrons in the rate of neutron gain, the increase in flux is governed by the generation time of delayed neutrons. The increase takes place slowly, over minutes, and can be detected and counteracted by the reactor control system.

A knowledge of the kinetic processes is essential for the safe design of a reactor. Computational treatment includes the simulation of individual processes and the linking of these over time.

1.3.8. Reaction Rates

The various reaction rates in the reactor are determined with the aid of the normalized neutron flux. They can be calculated as integral quantities or separately per energy group, subregion of the reactor, and nuclide. The reaction rates give an insight into what is happening in the reactor in terms of neutron physics. They also enable computer modeling of the variations in nuclide concentrations during power generation.

For example, the fission rate of the nuclide ^{235}U is:

$$R_{\mathrm{f}}\,(235\mathrm{U}) = \sum_{\text{groups g}} \int_{\text{reactor}} \Sigma_{\mathrm{f,g}}\left(235\mathrm{U},\ \vec{R}\right) \cdot \Phi_{\mathrm{g}}\left(\vec{R}\right) \cdot \mathrm{d}V$$

The sum of the fission rates for all nuclides gives the integral fission rate R_{f}. The ratio of this quantity to the integral flux Φ from Equation (4) defines a mean macroscopic fission cross-section $\Sigma_{\mathrm{f}} = R_{\mathrm{f}}/\Phi$, so that the integral fission rate can be written as $R_{\mathrm{f}} = \Sigma_{\mathrm{f}}\Phi$. The rates of other nuclear processes are calculated in a similar way.

A central reactor characteristic is the *neutron multiplication factor* k_{eff} :

$$k_{\mathrm{eff}} = \frac{\nu\Sigma_{\mathrm{f}} \cdot F}{\Sigma_{\mathrm{a}} \cdot F + L} = \frac{\text{Rate of production of neutrons}}{\text{Rate of loss of neutrons}}$$

This is the ratio of the integral production rate to the rate of loss. The latter is the integral absorption rate plus the leakage rate L of neutrons escaping from the reactor. For a steady-state chain reaction in which the number of neutrons neither increases nor decreases, $k_{\mathrm{eff}} = 1$ (criticality condition).

Since the absorption of a neutron is accompanied by a simultaneous nuclear transformation, the reaction rates also describe how the nuclide concentrations vary. The absorption rate

$\Sigma_a(\text{fiss})\Phi$ describes the consumption of fissile nuclides per second. The production of new fissile nuclides is given by the absorption rate of fertile nuclides (^{232}Th, ^{234}U, ^{238}U, ^{240}Pu) or the decay rate of intermediate product nuclides (^{233}Pa, ^{239}Np; see Fig. 3). The ratio:

$$\text{BR} = \frac{\text{Production rate of fissile nuclides}}{\text{Rate of loss of fissile nuclides}}$$

characterizes the fissile balance of the reactor. In most thermal reactors, BR is in the range 0.5 – 0.8 and is called the *conversion ratio*. In reactors with BR ≥ 1, chiefly fast reactors, BR is called the *breeding ratio* and the reactor is referred to as a breeder reactor.

The physical events in a reactor can be understood by interpreting the reaction rates (Table 7). Approximately half the neutrons are absorbed in the fissile nuclides to sustain the chain reaction. About 30 % are absorbed in fertile material, leading to the formation of new fissile material. About 20 % represent unavoidable neutron losses in the reactor materials (in fission products, moderator, control means, fuel cladding, reflector). The amounts of fissile and fertile materials are fixed so that the relative loss rates add up to 100 %, that is, the criticality condition is satisfied.

The breeding effect can be enhanced by a particularly favorable programming of the neutron balance. This is achieved by closing the fuel cycle, that is, reprocessing unloaded fuel assemblies and reusing fissile material. Thermal reactors benefit from employing ^{232}Th as the fertile material and reprocessing the fuel assemblies frequently [37]. In this way, the favorable fissile nuclide ^{233}U is allowed to accumulate (Table 3), and neutron absorption in the fission products is reduced. Fast reactors are loaded with plutonium as fissile material. Plutonium has good fission properties at high neutron energies. In this energy range, parasitic absorption by reactor materials is slight, and ca. 14 % of the fissions are fast fissions in ^{238}U. Thus, the consumption of fissile nuclides (i.e., the loss rate) is accordingly reduced. Leakage losses are reduced by the use of a fertile blanket in the reflector region.

1.3.9. Burnup and Control

In the narrow sense, burnup is the energy produced in the fuel divided by the mass of heavy metals (fissile and fertile material) used. Fissions of nuclides bred in the reactor are included. Burnup is expressed in units of MW · d/kg$_{\text{hm}}$ (hm = heavy metal). The total energy content of 1 kg of heavy metals is 921 MW · d/kg (available energy in ^{235}U). Various reactor designs provide for 0.7 – 10 % burn-up (i.e., fissioning) of the heavy metals (see Table 1).

More broadly, burnup embraces all nuclear transformations in the reactor: fission, neutron capture, and decay. Some 820 fission products and about 100 heavy-metal nuclides are formed and transformed. Many of these influence physical processes in the reactor and are important for safety. If the spatial distribution of the neutron flux is known, the formation of these nuclides and their decay history in the fuel assemblies can be modeled [38].

For each nuclide, the time dependence of its concentration N is found from the balance equation:

$$\mathrm{d}N/\mathrm{d}t = \text{Rate of production} - \text{Rate of destruction} \tag{5}$$

Through the absorption rate $N\sigma_a\Phi$ or the decay rate λN (λ being the decay constant in s^{-1}), the destruction of nuclides leads to the formation of new ones. Production is due to fission, neutron capture, or the decay of parent nuclides. As a result, the burnup equations (Eq. 5) for the individual nuclides are coupled to one another.

During reactor operation, the fissile content of the fuel assemblies decreases and the content of fission products increases. Some of these fission products have large absorption cross-sections. Two approaches are taken to maintaining the criticality condition $k_{\text{eff}} = 1$: In reactors with *continuous refueling*, old fuel assemblies with high burnup are continuously removed during operation, and fresh assemblies are loaded in their place. In reactors with *periodic refueling*, the fissile content is highest at the start of an operating cycle, and absorber material is added. The absorber is gradually withdrawn as burnup increases. Absorber rods, absorber solution in the coolant, and burnable absorbers are used. An example of a burnable absorber (control poison) is the nuclide ^{10}B, which has a large absorption cross-section (Table 5); it is burned up by neutron capture and transformed by an (n, α) process to ^{7}Li, which is virtually nonabsorbing.

Table 7. Neutron balances per fission neutron, in percent, and the conversion or breeding ratio

Neutron balance	Without recycle of fissiles		Closed fuel cycle	
	LWR	HTR	HTR ∗	FBR
Absorption in fissile material	48.0	52.0	45.9	36.5
Fission in other actinides	2.3	0.2	0.1	6.1
Capture in fertile materials	27.7	30.0	39.5	45.3
In other actinides	1.1	1.3	2.8	0.4
In fission products	6.8	7.7	5.4	2.3
In reactor materials and control poison	10.6	1.7	2.1	5.9
Leakage, control poison in reflector	3.5	7.1	4.2	3.5
Total	100.0	100.0	100.0	100.0

Slowing down to thermal energy	66.1	60.7	61.1	0.0

∗ ^{232}Th as fertile nuclide.

The differing properties of fission products are a factor in real load- changing operation and must be continuously corrected by the control system. The process can be explained for the most important example, the buildup of ^{135}Xe. In equilibrium operation, 98.6 % of this nuclide is produced by the decay of ^{135}I and only a small fraction directly by fission (Fig. 3). Xenon-135 is destroyed chiefly by neutron absorption (because of its large cross-section; see Table 5) and partly by decay. A reduction of reactor power is achieved by a decrease in the neutron flux. As a result, the rate of destruction of xenon decreases, whereas the rate of production by the decay of iodine initially remains unchanged. After a few hours, the iodine concentration slowly declines and the production rate of ^{135}Xe falls off. The relative absorption rate varies along with the xenon concentration (Fig. 8). To maintain the criticality condition $k_{\text{eff}} = 1$, the varying neutron absorption in the transient period must be compensated by withdrawing and later inserting the control rods. In normal operation, the control rods must be inserted partway to maintain a reactivity reserve so that the reactor can be controlled under load-changing conditions.

Computer simulation of reactor operation involves a frequent alternation of neutron-flux and burnup calculations, adjustment of control poison, and insertion and removal of fuel assemblies. In this way, the burnup and isotopic composition of the discharged fuel are determined. The need for new fuel is calculated, and the load history of the fuel assemblies is determined. In addition, the simulation can reproduce all operating states for detailed study so that reactor safety can be ensured.

The explicit calculation of the burnup history, can be restricted to those nuclides that are of marked importance for neutron absorption and the fissionable balance. These include about 15 actinides and some 50 fission products. On the other hand, all nuclides must be calculated when the radioactivity of the irradiated fuel is to be determined.

Figure 8. Neutron absorption of ^{135}Xe on a decrease in LWR output (a) to 40 %; (b) to 20 %

1.3.10. Fission Products and Actinides [40]

The threat posed by radioactive waste products is offbalanced by the utility of nuclear energy. However, the isolation of radioactive waste from the environment is an urgent problem that demands a great engineering effort. The concerns involved are reactor safety while the fuel assemblies are in the reactor and waste disposal after they are unloaded. The corresponding effort with fossil energy sources is very slight in comparison because, to a great extent, the waste from combustion processes can simply be discharged to the environment.

Inside the reactor, the containment of fission products, actinides, and activated materials is performed by multiple barriers: the fuel

cladding, the confinement of the coolant loop, and the reactor containments (Fig. 1). The objective of safety engineering is to protect these barriers against attack by mechanical, chemical, and especially thermal action.

On reactor shutdown, whether deliberate or initiated by the control devices, the output of energy from nuclear fission stops, but heat produced by the decay of fission products continues. Averaged over the first hour, this heat output is ca. 2 % of the previous reactor power and it decays slowly (Fig. 9). Integrated over the first 24 h, it matches 11 min of reactor output. This decay power is transferred to the coolant and moderator that surround the fuel assemblies, thereby heating these materials. The decay power must be removed to prevent overheating and failure of the fuel cladding.

In present reactors, decay power removal is accomplished by active technical means that are designed with multiple redundancy. In small reactor units for modular construction, now under development, decay power is removed by natural circulation of the coolant. Here, in the case of a break in the coolant loop (the second of the barriers listed above), decay power can still be removed without the use of active technical means: in liquid-cooled reactor designs by virtue of the enclosing containment vessel; in gas-cooled reactors by conduction in the graphite (see Section 1.2).

After being unloaded from the reactor, the fuel assemblies are placed in sealed containers and held in intermediate storage for some years. This time allows a large fraction of the fission products to decay, generating a decay power of 1 – 10 W/kg_{hm} (Table 8). After this, the fuel is either reprocessed or transferred to an ultimate storage facility. Reprocessing recovers the fissile material; the waste is vitrified, sealed, and also placed in ultimate storage.

Figure 9. Decay power after reactor shutdown (HTR module)

* 1 Ci = 3.7×10^{10} Bq (see Section 2.3.1).

Most of the fission products decay in the first decades; decay of the long-lived ones, such as ^{137}Cs and ^{90}Sr with half-lives of ca. 30 years, will be completed after a 1000 years. The actinides and their daughter products have comparatively low activities; however, these nuclides require safe confinement over several million years. Thus, ultimate storage facilities are sited, for example, in salt formations that have proved to be stable over geological spans of time. A concept developed in Sweden [40] provides for storage at a depth of 500 m in granite formations. In addition, studies are being conducted on the reuse of actinides in nuclear reactors [41] in order to convert them to short-lived nuclides by neutron-capture reactions. Of course, realization of this concept requires major development in reactor design, reprocessing, and recycling technology.

2. Power Reactors, Survey

2.1. Introduction, Scope of Utilization

Power reactors serve to supply energy. Approximately 200 MeV (3.2×10^{-11} J) of energy is released per nuclear fission (see Chap. 1) [42], [43]. Although this energy is emitted at first as the kinetic energy of the two daughter nuclei (ca. 165 MeV), the kinetic energy of the neutrons generated (ca. 5 MeV), and as β and γ radiation, it is largely converted into heat within the fuel itself. Only a small part of the energy produced (generally < 5 %) leaves the reactor in the form of γ or neutrino radiation.

Today, the heat created in power reactors is used predominantly in nuclear power plants for the production of electrical energy. Other uses include the production of process heat for industry (see Section 3.2.3.7), for the desalination of sea water [44], or for district heating [45] and exploitation of the energy for propulsion purposes (particularly for nuclear-powered ships [44]). A combination of several applications is also possible.

Nuclear-powered ships represent one of the oldest uses of nuclear energy. In fact, the Mark I prototype for the submarine *Nautilus* was put in operation in early 1955. Since then, numerous warships – but only a few civilian ships (NS *Lenin*, NS *Savannah*, NS *Otto Hahn*, NS *Mutsu*,

NS *L. Breschnew*, NS *Sibir*, NS *Rossia*, NS *Taymyr*, and NS *Vaygach*) – have been equipped with nuclear power units. Today old nuclear powered submarine wreckages of the former Soviet Union represent a possible source of radioactive pollution in the polar regions of the Atlantic ocean. Commercially, nuclear-powered ships have not gained acceptance because at the normal driving power of up to 73 500 kW (100 000 metric HP), fuel costs do not compensate for the comparatively high price of the nuclear units. Besides, many legal problems (dockage licenses, liability questions, etc.) remain to be clarified.

Nuclear process heat has also not been widely used. Although industry requires both low-temperature ($T < 300\,°C$) and high-temperature process heat [45], the high-temperature processes are either still being developed or undergoing testing. In addition, efficient heat transport requires that the reactor be located near the factory, which is, in turn, generally close to a city. Until now, the location of nuclear plants close to cities has been avoided as much as possible.

The same applies to the use of nuclear energy or its waste heat for district heating [45], [46]. Since domestic heating accounts for about 50 % of the energy consumption in industrial nations, power-heat coupling is of tremendous importance as far as energy politics are concerned. However, the heating energy to be decoupled can be transported only over relatively short distances (ca. 50 km) because of the losses incurred. This means that nuclear heating plants must be located in populated areas to be economical.

For these reasons, commercial reactors are used mainly for the generation of electricity in stationary nuclear power plants. A schematic representation of a nuclear power plant with a pressurized-water reactor (PWR) is given in Figure 10. In this case, the reactor core consists of square fuel assemblies, which are placed side by side (see Fig. 18). The fuel assemblies are composed of individual fuel rods that are approximately 1 cm thick. The fuel rods contain pellets of uranium dioxide with a ^{235}U enrichment of 3 – 4 %. A zirconium alloy serves as cladding material for the rods. Heat produced in the fuel elements is removed by the coolant in the primary loop and transferred to the secondary loop (working cycle) in the steam generators. Waste heat is dissipated by means of a cooling tower or a river (see Fig. 10).

The economic motivation for building nuclear power plants is the high energy content of the nuclear fuel uranium and its comparatively low cost: 1 kg of uranium (with 3 % ^{235}U) produce 2.5×10^9 kJ and cost about \$ 630 in the form of uranium hexafluoride (UF_6) in 1996. In comparison, 1 t of oil produce about 4×10^7 kJ and cost approximately \$ 157 in 1996. Thus, the specific cost of uranium $\$\,2.5 \times 10^{-7}$/kJ is lower than the corresponding cost of oil $\$\,3.9 \times 10^{-6}$/kJ or other fossil fuels by a factor of ten. Although this does not include the costs involved in fuel processing, the higher costs of erecting nuclear power plants, and the reprocessing or disposal costs, nuclear power plants are more economical for a wide range of output and load than conventional power plants [44], [48], [49].

The first large-scale nuclear power plant went on-line at Calder Hall (United Kingdom) in 1956. It consisted of four graphite-moderated, carbon dioxide-cooled Magnox reactors (see Section 3.2.2.1) with a total electric output of 220 MW_e. The first large pressurized-water reactor (see also Section 3.1.1), the Shippingport reactor in the United States (140 MW_e), was put in operation in December 1957. However, the birth of commercial nuclear power plant technology is considered to be the Oyster Creek event: i.e., the installation of a 640 MW_e boiling water reactor in the United States at the end of 1963, without governmental assistance and according to purely commercial aspects. Although the total electrical output of all nuclear power plants on order, under construction, or in operation, increased almost exponentially (output doubled ca. every 2 years) until the mid-1970s, this value has remained virtually constant since 1975. At the same time, the number of operating nuclear power plants increased due to the completion of plants that were under construction. In contrast, the number of plants on order decreased, especially after the accidents at Three Mile Island (1979) and Chernobyl (1986). However, an increase in construction is anticipated because of increasing electricity demands, the carbon dioxide problem, and the replacement of old nuclear power plants ([49–52]).

In Figure 11, the total electric capacity of nuclear power plants of a particular type on or-

Figure 10. Basic configuration of a nuclear power plant with a pressurized-water reactor [47]

der, under construction, or in operation is plotted logarithmically against the year ([47], [53]). Different types of reactors are described in the following sections.

At the beginning of 1996, 426 nuclear power plant units with a total output of 344 422 MW_e were in operation worldwide, and 39 additional nuclear power plants with a capacity of 32 594 MW_e were under construction or planned [54]. However, the percentage of electric power drawn from nuclear reactors varies considerably from country to country. It ranges from approximately 2 % (China, India), through 30 % to 45 % (Germany, Finland, Japan, Spain, Rep. of Korea, Switzerland and Sweden), up to 75 % and 85 % (France, Lithuania). In 1996 nuclear energy account for about 7 % of the worlds' primary energy consumption.

2.2. Important Technical and Economic Parameters

The costs of electricity generation in a nuclear power plant are related to the following factors (see, e.g., [42], [44]):

1) The *specific cost of the plant* k_p, which depends on the type of reactor and the size of the power plant, is usually expressed in terms of dollars per kilowatt of electrical output. In 1997, a 1300-MW nuclear power plant with a pressurized-water reactor would be expected to have a k_p of about \$ 2000/kW.
2) *Plant utilization* (*load factor*) f which is the ratio of the energy actually produced (in one year) to the maximum possible energy production.
3) The *thermal efficiency factor* η ($\eta = P_e / P_{th}$) is the ratio of electric (P_e) to thermal (P_{th}) output. A distinction is made between the net and the gross efficiency, depending on whether or not the internal electric consumption of the power plant has been deducted. The factor η is determined basically from the condition of the steam in front of the turbine (steam pressure p_{St}, steam temperature T_{St}) and depends largely on the average reactor coolant temperature as a result of heat transfer in the steam generator.
4) The *specific fuel cost* k_F covers the costs of the finished fuel assemblies in dollars per kilogram of uranium used. For reactors that contain thorium or substantial amounts of plutonium, in addition to uranium, this factor is related to 1 kg of heavy metal (hm = U + Th + Pu). The fuel costs are made up of the cost of the natural uranium (or thorium) required, the enrichment costs, and the expenses involved in fabrication of fuel assemblies. In 1997, k_F values of about \$ 1000/kg uranium (3 % ^{235}U) are expected for a pressurized-water reactor. In addition, repro-

Figure 11. Total worldwide electric capacity of nuclear power plants in operation, under construction, or on order [47], [53] a) Pressurized-water reactors (PWR); b) Boiling-water reactors (BWR); c) Light-water cooled graphite-moderated reactors (LWGR); d) Heavy-water reactors (D_2O); e) Gas-cooled graphite reactors (GGR; including Magnox and advanced gas-cooled reactors); f) Fast breeder reactors (FBR); g) High-temperature reactors (HTR)

cessing and disposal costs ($k_R \approx \$\,2000$/kg uranium, in 1997) have to be considered.

5) The *average specific power* q_{sp} ($q_{sp} = P_{th}/M_F$) is the ratio of the thermal power output P_{th} of the reactor to the fuel mass M_F. In general, q_{sp} is expressed in terms of kilowatts per kilogram of uranium or heavy metal. The average specific power q_{sp} depends on the maximum permissible power density in the fuel q'''_{max} and on the ratio of maximum to average power density (i.e., the power form factor F_Q). If the fuel density is ϱ_F (in the case of UO_2, e.g., 10.35 g/cm^3), then

$$q_{sp} = \frac{q'''_{max}}{F_Q \cdot \varrho_F}$$

$$F_Q = \frac{q'''_{max}}{q'''}$$

The power form factor F_Q is determined by the shape of the neutron-flux density Φ. (For a definition of neutron-flux density, see Section 1.3.6).

The following relation applies:

$$q''' \left[\mathrm{J\,m^{-3}\,s^{-1}}\right] = \chi \Sigma_f \Phi$$

where $\chi = 3.2 \times 10^{-11}$ J is the energy per fission; Σ_f the macroscopic fission cross-section (m^{-1}); and Φ the neutron-flux density (m^{-2} s^{-1}). The maximum power density q'''_{max} is limited by maximum permissible temperatures. The following limits are important:

a) The maximum (central) fuel temperature T_0. In the case of cylindrical fuel rods, as in Figure 12, the heat produced per unit of length is described by the *specific fuel rod power* q':

$$q' = 4\pi \cdot \int_{T_1}^{T_0} \lambda(T)\,\mathrm{d}T$$

where λ is the heat conductivity and T_1 is the fuel pellet surface temperature. The fact that T_0 must remain below the melting temperature of the fuel results in a limiting value for q'. For fuel rods made of uranium dioxide (independent of the radius of the fuel rods and practically independent of the type of reactor), q' must be ≤ 650 W per centimeter fuel rod.

b) The maximum heat flux density $q''_{\max}$ at the surface of the fuel rod. In pressurized-water reactors, a film of steam may develop between the surface of the fuel rod and the coolant if the heat flux density is too high (socalled DNB = departure from nucleate boiling). The transfer of heat would then be impeded, and the cladding tube would be overheated. In pressurized water reactors, the required protection from film boiling limits the maximum possible heat flux density $q''_{\max}$ to approximately 200 W/cm^2.

Figure 12. Temperature distribution in a fuel rod [42]
a) Fuel (UO_2); b) Gap; c) Cladding
T = temperature; r = radius; Clo = cladding outside; Cli = cladding inside; F = fuel; C = coolant

For cylindrical fuel rods with radius r_F and a constant power density within the fuel rod, the power density q''', the heat flux density q'', and the specific fuel rod power q' are related as follows:

$$q' = 2\pi r_F \cdot q'' = \pi r_F^2 \cdot q'''$$

Thus, a limit for $q'''_{\max}$ results from the energy output limits for q' and q'' given above.

6) The *burnup B* (see Section 1.3.9) is the thermal energy produced per kilogram of uranium (or heavy metal) during the time of use in the reactor (burnup is usually expressed in the units kW · d/kg U or MW · d/t U). Because each fission releases about 200 MeV (3.2×10^{-11} J) of energy, burnup can also be expressed as FIFA (fissions per initial fissile atoms) or FIMA [fissions per initial (heavy) metal atoms].
The burnup attainable is limited by factors relating both to neutron physics and to the construction materials used. The fuel starts to swell at a higher burnup because of the resulting fission products. This, in turn, can cause damage to the cladding tube (see Section 3.1.4.1). From the standpoint of neutron physics, the burnup of fissile material and the increased poisoning with fission products result in a loss of reactivity (see Section 1.3.9). The material limitation is the limiting factor in most types of reactors. From the point of view of neutron physics, the reactor is generally designed so that the maximum permissible material-dependent burnup is achieved by selecting a suitable initial enrichment (reactors operating with natural uranium are an exception). Because of the location-dependent power density distribution in the reactor, a distinction must be made between the average burnup of a fuel element (or a batch of fuel elements) and the maximum, local burnup.
7) In addition, the costs of electricity generation in a nuclear power plant are influenced by *economic factors* such as depreciation periods and interest rates.

In a nuclear power plant with a pressurized-water reactor, about 70 % of the cost of electricity generation in 1997 was accounted for by investments (depreciation and interest), about 20 % by the fuel (stock and consumption), and about 10 % by the operation.

The following ratios are important for the costs of electricity generation:

k_p/f	for plant costs
$k_F/f\,\eta\,q_{sp}$	for the fuel stock
$k_F/B\,\eta$	for fuel consumption

Table 11 gives a survey of the technical data of some nuclear power plants.

2.3. Radiation Protection and Safety

2.3.1. Radiological Quantities and Units

The α, β, and γ particles generated in nuclear reactors predominantly cause excitation and ionization of atoms or molecules. In this process, electrons are transferred to higher energy levels or removed completely. In complex organic molecules, this leads to the distortion or cleavage of chemical bonds and to the formation of aggressive free radicals, which, in turn, can alter or damage biological macromolecules. Although neutrons cannot interact directly with electrons because of their electrical neutrality, indirectly they are just as active as charged particles via collision and capture processes with the nuclei. In addition, subsequent γ disintegration of the target nucleus or (n, p) and (n, α) reactions can cause chemical transformations, whereby nucleic acids and enzymes are altered.

Radiation damage is approximately proportional to the energy absorbed. Consequently, the most important radiological quantity is the *energy dose D*, which is the radiation energy (of any type) absorbed per kilogram of any substance. The unit of measure is the gray (Gy): 1 Gy = 1 J/kg (the old unit rad is still frequently encountered; 1 rd = 10^{-2} Gy).

However, the biological effect of radiation depends not only on the energy dose, but also on the type of tissue affected and on the manner in which the total energy absorbed per kilogram is distributed spatially and over time. The *energy dose rate* $\dot{D}$, i.e., the absorbed energy per kilogram and second (units: W/kg, Gy/s, mGy/h; or the old units: rd/s, mrd/h, etc.), serves as a measure of radiation exposure per unit time.

The spatial distribution of molecular damage depends on the nature of the radiation. For example, α particles and protons have a substantially shorter range than β particles (electrons) of the same energy because the former have a much larger mass and a correspondingly lower speed. They release their energy along a much shorter path and thus generate a much higher ionization density than β and γ particles. Hence, the molecular damage produced by β or γ radiation is distributed more evenly over the tissue than in the case of an equal energy dose of the heavy corpuscular radiation. Thus, biological damage depends not only on the dose of energy but also on the nature of the radiation. The *dose equivalent* D_q has been introduced as a measure of biological damage:

$$D_q = q \cdot D$$

The dimensionless quality factor q is used to express the relative biological effectiveness of a certain type of radiation compared with γ-rays. Thus according to the definition, $q = 1$ for γ quanta. Quality factors for other types of radiation may be summarized as follows [55], [56]:

β and γ radiation	1
p (energy dependent)	1 – 15
α radiation (energy dependent)	10 – 20
heavy recoil nuclei	20
n, thermal	2.3
n, 5 keV	2.0
n, 20 keV	3.3
n, 100 keV	7.4
n, 1 MeV	10.6
n, 10 MeV	6.8

The dose equivalent D_q is measured in joules per kilogram. However, the special unit sievert (Sv) is also used for D_q, which eliminates any confusion between D and D_q. Therefore,

$$D_q\,(\mathrm{Sv}) = q \cdot D\,(\mathrm{Gy})$$

Correspondingly, the following equation applies to the *equivalent dose rate*:

$$\dot{D}_q = q \cdot \dot{D}$$

$$(\text{units}: \mathrm{W/kg\ or\ Sv/s,\ mSv/h,\ etc.})$$

An old unit for the dose equivalent, which is still encountered frequently in the literature, is the rem (**r**ad **e**quivalent **m**an): 1 rem = 10^{-2} Sv.

In addition to the dosage units mentioned above, the *ion dose J* is a measure of the charge produced per kilogram of air by ionizing γ radiation [units: C/kg or (old) roentgen (R), 1 R = 258×10^{-6} C/kg]. This is the oldest radiological unit, it is applicable only to γ or X-rays and is material related. Because the ionization potential of the air is known (34.0 eV), the ion dose can be converted into the energy dose. The following applies to air: 1 C/kg = 34 Gy (1 R = 0.87 rd), and to body tissues: 1 C/kg = 39 Gy (1 R $\approx$ 1 rd).

Furthermore, the activity A is of considerable importance. It is the number of radioactive disintegration processes per unit time and is measured in becquerel (Bq): $1\,\mathrm{Bq} = 1\,\mathrm{s}^{-1}$. The old unit curie (Ci) is still used frequently: $1\,\mathrm{Ci} = 3.7 \times 10^{10}\,\mathrm{Bq}$.

2.3.2. Radiation Burden, Radiation Damage, Radiation Safety Rules and Regulations

2.3.2.1. Natural and Medical Radiation Doses

Natural exposure results from cosmic radiation (elevation dependent); terrestrial radiation due to radioactive elements in the earth's crust, especially in rocks (location dependent); and the intake of natural radioactive isotopes with air and drinking water (internal radiation burden). For instance, the average value in Germany is approximately 2.0 mSv/a = 200 mrem/a [56], [57]. However, considerable deviation is observed, depending on location; e.g., the external radiation burden arising from cosmic rays at an elevation of 3000 m is 1 mSv/a and at 6000 m more than 6 mSv/a (compared to ca. 0.3 mSv/a at sea level). Local deposits of radioactive minerals and rocks have an even stronger effect. Values up to 120 mSv/a have been measured at individual locations. Apart from the natural radiation burden, the radiation exposure connected with various *medical procedures* is of special importance and interest. For example, these are approximately 0.3 mSv from a lung X-ray, 1 – 4 mSv from a pelvic X-ray, and up to several sieverts from γ radiation in cancer therapy [56].

2.3.2.2. Radiation Damage and Radiation Safety Regulations

The *somatic damage* caused by higher radiation burdens is presented in Table 9 for the worst case (one-time exposure of the entire body). No direct damage can be observed up to a dose equivalent of 0.25 Sv. Clinical symptoms appear at dosages higher than ca. 0.25 Sv, and subjective complaints set in above ca. 1 Sv (100 rem).

Table 9. Medical symptoms following whole-body exposure to different doses of radiation

Dose, Sv	Symptoms and their consequences if no medical treatment is given
0.25	(hazardous dose) changes in blood count detectable; no subjective complaints
1	no definite symptoms detectable at first; loss of appetite, nausea, exhaustion, diarrhea and moderate marasmus after three weeks; recovery of the patient is probable; chance of death in individual cases
4	nausea and vomiting 1 – 2 h after exposure to radiation; symptoms soon disappear, only to reappear in a more severe form after 2 weeks, together with symptoms described above; other complaints: fever, severe inflammation of mouth and throat, and nasal bleeding; 50 % chance of survival
6	course of the disease similar to that described above; interval without marked symptoms is shorter; virtually 100 % chance of death

A typical characteristic of radiation sickness is that irradiation is followed by a longer or shorter latent period without defined symptoms, the duration of which depends on the radiation dose. This period can last a few days, even in the case of the virtually 100 % lethal dose of 6 Sv. The latent period is caused by the fact that radiation damages particularly the cells of hematopoietic organs (bone marrow and lymphatic tissue) and, consequently, interferes with or totally stops the supply of red and white blood cells. However, this lack of replenishment comes to light only after the death of the cells still present in blood. In a similar manner, the otherwise continuous renewal of the intestinal mucosa is prevented. The results are diarrhea, anemia, increasing weakness, and inability of the body to fight additional infections.

Apart from the hematopoietic organs, the intestine, skin, and growing bones (i.e., parts of the body that undergo rapid cell division), the reproductive glands are particularly sensitive to radiation. Chromosomes and genes can be damaged, and genetic traits can be altered (*genetic damage*). Also, the statistical long-term risk of leukemia and other forms of cancer increases slightly with increasing doses of radiation (*long-term damage*). The radiation-induced probability of getting cancer is, however, generally small compared to the natural incidence of this disease. The spontaneous frequency of cancers in the industrialized countries of the Western world is about 20 % (i.e., 20 % of all people die from cancer). On the other hand, the risk of getting cancer from radiation in doses of up to 1 Sv is reported

to be 0.07 per sievert [58], [59]. Therefore, in the case of a total dose of 0.1 Sv (10 rem), the additional radiation-induced incidence of cancer would amount to 0.7 % (compared to 20 %).

The information presented above shows that radiation exposure up to a few hundredths of a sievert per year is harmless to the health of the individual. In contrast, the statistical risk of the occurrence of hereditary defects and certain diseases (long-term damage) increases slightly but continuously with increasing doses of radiation. Although this additional risk generally remains negligibly small for the individual compared with other risks in life, it could, however, become important when larger parts of the population are exposed to an increased radiation burden.

For this reason, the ICRP (International Commission on Radiological Protection) has drawn up recommendations for a *radiation protection law* [55] and is revising them constantly. This law is based on the ALARA (**a**s **l**ow **a**s **r**easonably **a**chievable) principle. These regulations have been accepted by governmental organizations of individual countries [60–63] and represent binding, national law. The German radiation protection regulation (StrlSchV) [64], for example, is based on the principle that the radiation burden of the *entire population* must remain as low as possible and must not exceed the range of the natural radiation burden. On the other hand, *special regulations* apply to persons who are exposed to radiation in the course of their work. These are based on a maximum annual exposure of 50 mSv.

For the general population outside a control area, the annual dose equivalent must not exceed 0.6 mSv, of which the contribution by air or water is limited to 0.3 mSv each. Experience has shown that the actual annual radiation burden in the vicinity of a nuclear power plant is approximately 0.01 mSv.

The permissible doses and dose rates for the irradiation of parts of the body can be larger (the dose rate for occupationally exposed persons is e.g., 300 mSv/a for the thyroid and 500 mSv/a for the hand). Other limiting values for practical radiation protection (e.g., limitation of the occupational lifetime dose to 0.4 Sv) are being discussed continuously and updated in national regulations (see e.g., [64], [65]).

Because of the relationship between dose rate, neutron or γ-flux density, and activity, limiting values for the neutron- and γ-flux densities, for the maximum permissible activity input into a body, and for the concentration of radioactive substances in air and water are also obtained from the maximum permissible dose rates. The activity concentration K is deduced from the particle concentration N and the radioactive disintegration constant λ_{D} according to the formula

$$K = \lambda_{\mathrm{D}} \cdot N$$

Numerical values can be obtained from the corresponding radiation protection regulations.

2.3.3. Emission Protection

All nuclear reactors are surrounded by *concrete shielding* (several meters in thickness), as a protection barrier against direct neutron and γ radiation from the reactor core. Thus, direct radiation plays no role outside the nuclear plant. On the other hand, the emission of gaseous and liquid radioactive substances into the surroundings cannot be completely avoided. Emission protection devices serve to maintain the radioactive environmental burden below the maximum permissible values. This results in important restrictions concerning maximum permissible activity emissions per unit of time.

According to international law, *liquid radioactive waste* may be drained off into the surroundings only if the activity concentration of the water discarded has a dose equivalent rate $\dot{D}_q \leq 1.5$ mSv annually, even if the water is permanently used as drinking water, bathing water, etc. Even lower limiting values are set in some countries, e.g., the 0.6 mSv- concept in Germany [64].

The maximum permissible emission of *activity via the stack* of the power plant is determined by the aforementioned maximum dose rate allowed in the surroundings of the plant and from the dissipation of activity in the atmosphere. Special directives apply to the calculation of activity dissipation [56]. On the basis of these ratios, licensing authorities stipulate maximum values for the annual permissible activity emission for each nuclear power plant.

The main sources of radioactivity in nuclear power plants are:

1) *Fission products* that arise from nuclear fission in the fuel (see Table 59) and their daughter products; and
2) Nuclei activated by neutron capture, the *activation products*, which develop primarily in the coolant and from impurities therein (corrosion products).

Although the fission products remain for the most part within the fuel elements, a small part of the more mobile isotopes (mainly noble gases, iodine, etc.) can diffuse out of the fuel and enter the coolant through defects in the cladding tube. Even though most of the fission and activation products are removed in coolant purification plants, a portion is still released into the surroundings with the wastewater and the exhaust air from ventilation units.

Emission via the Stack. The emission rate of noble gases via the stack is ca. 10^{13} Bq annually (mainly ^{133}Xe and ^{85}Kr) for a 1300-MW_e pressurized-water reactor. Smaller amounts of ^{131}I and aerosols (ca. 2×10^8 Bq/a) are also emitted. However, experience shows that the resulting real radiation burden for the population living in the vicinity of a nuclear plant, is far below the design value and, at ca. 1×10^{-2} mSv annually, amounts, e.g., to only about 1 % of the natural radiation burden in Germany. The path of exposure, pasture – cow – milk – thyroid gland, is considered to be the *critical path*. The intake of radioactivity via the food chain is called ingestion.

Radioactive wastewater is produced by leakage and, to a larger extent, in laboratories, laundries, etc. The methods used in processing wastewater are precipitation, filtration, evaporation, and ion exchange. Indeed, decontamination can be reduced by a factor of $10^4 - 10^5$ (excluding volatile constituents and ^{3}H) with modern evaporation plants. In this way, the activity (without ^{3}H) finally released into the surroundings can be limited to ca. $2\times10^7 - 7\times10^9$ Bq annually, with an additional annual tritium emission maximum of 3.7×10^{13} Bq (1000 Ci/a) in the case of large pressurized-water reactors. Retaining ^{3}H is practically impossible with conventional methods. Experience shows that the effective radiation burden on the population living in the vicinity of the plant due to wastewater is $< 1\times10^{-3}$ mSv/a (i.e., barely 1 ‰ of the natural radiation burden in Germany) [44].

A direct connection between an activity emission rate (Bq/a) and a radiation burden (mSv/a) cannot be made because the radiation burden of a human being depends on the amount of radioactive substances absorbed (which depends on location, weather conditions, etc.) and the special isotopes involved. However, with the help of meteorological dissipation factors a known emission rate (Bq/a) can be used to calculate the activity concentration (Bq/m^3) produced at a certain spot with a particular weather condition. This value, in turn, gives the particular radiation burden for a person at a definite rate of intake, a definite residence time (e.g., permanent residence), and a known isotopic composition. The average (or maximum) values for the annual radiation burden of the population in the vicinity of the plant can then be calculated by taking into account the statistical frequency of various weather situations and living conditions. The calculations are checked and supplemented by means of control measurements of the actual radiation burden in the vicinity of nuclear power plants.

Solid Waste. Apart from gaseous and liquid waste products, solid waste is also produced in the form of used ion-exchange resins, evaporator concentrates, filters, etc. In the case of a large pressurized-water reactor, a total of ca. 200 m^3 of low-, medium- and high-level waste is produced per year. This does not represent an environmental hazard if intermediate and final storage of the waste and spent fuel elements are properly conducted (see Section 5.5.4).

2.3.4. Industrial Safety

During normal operation, the radiation burden from a power plant is negligibly small (barely 1 % of the natural radiation burden). However, the question arises whether malfunctions could pose an environmental threat.

A nuclear explosion, as in the case of an atomic bomb, is basically impossible with a reactor because the reactivity decreases with increasing temperature and decreasing material density. Consequently, the chain reaction

would immediately stop itself (for special problems with fast breeder reactors and graphite-moderated light-water-cooled reactors, see Sections 4.1.3 and 3.3.3, respectively). However, the radioactivity remaining in the fuel elements represents a considerable potential threat. The release of a large part of the radioactivity contained in a reactor can have catastrophic consequences, as shown, for example, by the reactor accident in Chernobyl (see Section 3.3.6).

Therefore, the most important task of the technical safety equipment is to ensure that disasters of this type are impossible and to rule out even smaller malfunctions with adequate certainty. For this purpose, every reactor plant is provided with extensive safety devices, which are based on careful malfunction analyses [66]. A safety report must be submitted to the authorities before a reactor is put in operation. This report must contain an exact description of the plant with its safety facilities and must furnish proof that the plant will pose no threat to the surroundings.

Not only severe mishaps, but all malfunctions must be prevented in a nuclear power plant, hence safety measures are an integral part of a multistage concept. The individual levels of this concept are the operational systems, the protection systems, the safety systems, and the severe accident management.

All systems required for the operation of the plant in accordance with regulations (normal operation) are considered *operational systems*. All parts of the plant that protect the nuclear power plant or component systems from destruction during abnormal operation (see Section 3.1.3) are called *protection systems*. The function of the *safety systems* is to control possible malfunctions and to guarantee containment of radioactive substances. *Severe accident management* includes measures for the utilization of design reserves as well as operational and external facilities that are capable of reducing the consequences of an accident inside or outside the area of the power plant.

2.3.4.1. General Design Principles for Protection Systems

Inherent Safety. The reactor system must be designed in such a way that it returns to a safe state by itself in the case of malfunction. This occurs, e.g., because of the negative power coefficients of the reactivity (see also last paragraph of Section 1.3.4) and control rods that automatically shut down the reactor if there is a power failure.

Single-Error Criterion. A relevant technical safety system must fulfill its function as required even if, at the same time an additional single error causes the failure of components or parts of the system. Hence, essential safety devices are present several times (i.e., redundantly).

Redundancy. The installation of surplus units to increase reliability is known as redundancy. For the measurement of important parameters, for instance, 3 or 4 similar measuring channels are used whose signal techniques are independent of each other, spatially separated, and connected in parallel. One or two of these channels may fail without affecting the efficiency of the system. The same applies to many other components, (e.g., the pumps of the emergency cooling system).

Diversity. The diversity of protective measures refers to the installation of different protective devices, which serve the same purpose but are designed according to different principles and, as far as possible, are triggered by different physical variables (e.g., shutting down the reactor by using absorbing rods or by using liquid boric acid). Diversity is meant to exclude systematic errors that would not be prevented by the multiple use of identical protective devices.

Automation. All technical safety actions are triggered automatically by signals that come from various limiting value indicators. Here, the safety system has priority over all other systems and cannot be influenced by the operator. The components actively operated by the protection system are, in case of demand, independent of an external power supply.

Quality and Control. All safety facilities must meet special quality requirements, which include production controls and regular rechecks (automatically, if necessary).

Object Protection. In addition, the most important components of the individual safety systems are protected against forces from outside, such as an airplane crash, earthquake, explosion, or sabotage.

2.3.4.2. Safety Channels, Safety Limits, and Safety Measures

A safety system consists of (1) measuring elements for the detection of physical forward signals; (2) a signal processing and decision level for the processing of measured variables; and (3) limiting values, as well as sequentially arranged mechanical safety equipment, which is started by appropriate control signals. The measuring and decision parts form a safety channel that triggers one or more protective actions when permissible limiting values are exceeded. These values are selected in such a way that no dangerous operational parameter is reached.

Important *safety channels* cover, for example,

The thermal reactor output P_{th},
The reactor period $T_p = \Phi/\dot{\Phi}$ [especially important in the start up phase (Φ = neutron-flux density)],
The protection against film boiling in water-cooled reactors,
The coolant flow rate,
The system pressure,
The water level in the steam generators, and
The condenser pressure.

The most important *protective actions* are as follows:

The reactor scram (i.e., emergency shutdown),
The turbine emergency shutdown,
The response of various safety valves,
The emergency power supply,
The emergency feeding of the steam generators,
The emergency core cooling, and
containment (closing off the building).

2.3.4.3. Engineered Safeguards

The protective actions mentioned above are triggered by technical safety equipment, which may also include passive safety devices. The most important safety features of pressurized-water reactors are shown in Figure 13 [47]. The *passive safety elements* include (see Fig. 13):

1) the cladding tubes and the closed primary circuit (reactor cooling loop), which form the first and second barriers against the escape of fission products;
2) the biological shield (d) with the protective cylinder (e);
3) the gastight steel containment (g, wall thickness ca. 30 mm);
4) the secondary containment (h) made of concrete (wall thickness ca. 2 m); and
5) the accumulator (m), which contains borated water. In case of a serious loss of coolant, back-pressure valves permit quick and automatic feeding of sufficient quantities of water into the coolant cycle (8×20 % redundancy).

The steel containment is designed to hold the mass and energy of the primary coolant even in the case of a total loss of coolant. The steel containment is enclosed in a secondary concrete containment (h) to protect the surroundings from the direct radiation of the radioactive coolant. The annulus between steel and concrete containment is maintained at a subatmospheric pressure to prevent the escape of radioactive materials in the event of leakages.

The *active safety devices* of a pressurized-water reactor include (Fig. 13) the following:

1) Low-pressure residual heat-removing pumps (j). In the case of loss of coolant, these pumps deliver borated water from the borated water storage tanks (l) or, after they have been emptied, from the building sump via secondary coolers to the primary circuit. In case of a large leak, these pumps ensure cooling of the reactor core even after drainage of the pressure tank (4×50 % redundancy)
2) High-pressure safety feed pumps (i), which can feed against higher pressure and can flood the core if, in the event of a smaller leak, the system pressure drops relatively slowly (4×50 % redundancy)
3) The emergency power supply, consisting of batteries (s) and converters for the uninterrupted supply of important control and locking systems, etc. (2×100 % redundancy), as

Figure 13. Engineered safety features of Siemens/KWU pressurized-water reactors [47]
a) Reactor pressure vessel; b) Steam generator; c) Reactor coolant pumps; d) Biological shield; e) Internal concrete cylinder; f) Annulus ventilation system; g) Containment; h) Secondary containment; i) Safety injection pump (4×50 % redundancy); j) Residual heat-removal pump (4×50 % redundany); k) Residual heat-exchanger (4×50 % redundancy); l) Borated water storage tank (4×50 % redundancy); m) Accumulator (8×20 % redundancy); n) Intermediate cooler; o) Service cooling-water pumps; p) Main steam and feedwater valve compartment; q) Emergency generator; r) Demineralized water storage tank; s) Batteries (2×100 % redundancy); t) Emergency diesel engine (4×50 % redundancy); u) Fuel pool pump; v) Nuclear component cooling pumps; w) Emergency nuclear component cooling pumps; x) Emergency service cooling-water pumps; y) Extra borating pump; z) Rapid shutdown system
G = generator; fp = fuel pool

well as highly efficient, quick starting diesel engines (t) (4×50 % redundancy)
4) The control rod system for the reactor scram
5) Numerous safety valves, shutoff valves, and similar components that cannot be discussed here in detail

All possible mishaps can be controlled with the help of these generally multiple redundant safety devices. The special safety devices of other types of reactors are dealt with as each reactor is described.

2.3.5. Accidents

2.3.5.1. Classification and Analysis

Classification of the conditions of operation of nuclear power plants involves the following definitions (according to [66], [67]):

1) *Designated operation* includes
   a) Operational processes for which the plant with properly functioning systems (undisturbed state) is designed and to which it is suited (normal operation)
   b) Operational processes that proceed properly when components of the plant fail to function (disturbed state), as long as no

safety reasons exist for discontinuing operation (abnormal operation)

c) Processes involving control, testing, maintenance, and repair

2) *Malfunctions* are a course of events that require plant operation to be discontinued for reasons of safety, even though the plant has been designed for these events.

3) A range of conceivable events, called *accidents*, remains beyond the safety design of nuclear power plants. These include events that are, as far as anyone can judge, so improbable that specific measures for prevention or limitation of their consequences are not usually taken, or events whose occurrence and course are not foreseeable. In the event of accidents, limiting values for the radiation burden stipulated in radiation protection regulations can be exceeded.

The most important malfunctions include the following:

Mishaps dealing with reactivity (e.g., control rod ejection)
Disturbances in the core cooling system (e.g., because of pump failure or loss of coolant)
Disturbances in heat removal (e.g., because of load rejection or emergency shutdown)
Failure of secondary pipes

Conceivable *external causes of damage* are storms, storm tides, floods, earthquakes, explosions of plants or of means of transport in the vicinity (e.g., air crashes), and sabotage. Protection against external damage requires structural measures and precautionary action to be taken in the design of the technical systems. These measures are based on meteorological, geological, and transport-oriented expert opinions and experience.

The safety planning and assessment of a plant is based on an exact analysis of all possible malfunctions, courses, and effects of malfunctions, that is, of all conceivable chains of events including the corresponding probability of occurrence.

The probability of occurrence and the effects of any case of damage can be calculated in advance (*probability concept*) if all the independent individual probabilities are known. Indeed, a quantitative measure for the *risk of damage* $R_D = P_D \cdot D$, can be defined by multiplying the *extent of damage D* (e.g., quantified by the activity released or the radiation burden) by the probability P_D. In any event, this risk must be so low that for the people living in the vicinity of a nuclear power plant, the additional nuclear risk of damage is sufficiently small compared with the risk from other situations in life (illness, traffic accidents, etc.).

Until now, all investigations have shown that the *statistical risk* from nuclear power plants is negligibly small compared to other natural and civilization-dependent risks (see [43], [67–70]). The statistical risk also includes the reactor accident at Chernobyl, as shown in the evaluation of available data [70], [71]. Quantitative details on the relationship between the extent and probability of damage are presented in Figure 14.

	c) Railroad accidents
	d) Fires and explosions
FRG:	e) Late fatalities
	f) Early fatalities
Unites States:	g) Meteors

b) – d): actual occurrence; e), f): expectation for nuclear power plants

2.3.5.2. Design Accident

It is customary to design safety facilities according to the *maximum credible accident* (MCA). The MCA is defined as the accident that produces an effect, measured by the radioactive burden on the surroundings, that cannot be surpassed by any other credible accident during the lifetime of the plant. Frequently, the term *design accident* is preferred because it refers to the largest malfunction, which not only forms the basis for the design of safety devices but is also safely handled by them.

For a long time, a single maximum credible accident was considered relevant for all safety facilities. This was, for most types of reactors, a sudden loss of coolant that was defined, for example, in the case of a pressurized-water reactor, by a double-sided open break of the main coolant pipe. This amounts to a maximum leakage cross-section of about 0.5 m^2 (nominal diameter of the main coolant pipe is 750 mm) in reactors of the 1300-MW category. However, more recent experimental and theoretical studies have shown that a single design accident does not have the same significance for all safety devices. For instance, the double-sided open break in the main coolant pipe is considered to be an MCA only for emergency cooling, whereas otherwise, a malfunction spectrum with varying leakage cross-sections and points of breakage has to be taken into account.

2.3.6. Location Problems

The choice of suitable locations is becoming increasingly difficult because the demands for safety, profitability, and technical realizability (e.g., with respect to waste-heat removal) partly contradict each other. In nuclear power plants that exclusively generate electricity, consumer proximity is not an economic necessity. In fact, until now, remote locations have been preferred for these plants because of the large cooling water requirement. However, because rivers are only allowed to be heated to a limited extent for ecological reasons, cooling towers are increasingly employed.

In wet cooling towers, only the quantity of water that evaporates in the cooling tower must be replaced. Because of the large enthalpy of evaporation of water, the cooling water requirement is barely 2 % of the quantity required for direct river-water cooling. Dry cooling towers require no cooling water at all, but they need large heat- exchanging surfaces (increased construction volume) and a higher condenser temperature (decrease in thermodynamic efficiency).

Efforts made to find suitable locations for nuclear power plants either underground or at sea have not been successful so far.

In general, *consumer proximity* is required for the location of plants with power – heat coupling (e.g., for district heating). The problems that are still unsolved are mainly a result of the licensing procedures.

2.4. Survey of Reactor Types

2.4.1. Classification Features

Commercial reactors can be classified according to various characteristics:

Neutron energy:	thermal or fast
Fuel:	metallic or ceramic
Degree of enrichment:	natural or increased content of fissile material
Fissile material:	^{235}U, ^{239}Pu, ^{241}Pu, ^{233}U
Moderator:	H_2O, D_2O, C, or none
Coolant:	H_2O, D_2O, CO_2, He, liquid Na, etc.
Operational cycle:	direct circulation of the coolant between reactor and turbine or interconnection of a heat exchanger (e.g., a steam generator)

2.4.1.1. Neutron Energy Spectrum

The fast neutrons generated in nuclear fission (ca. 2 MeV average initial energy) are usually slowed down by a *moderator* (see Section 1.3.5) to thermal energies (< 0.1 eV) before they initiate new nuclear fissions. In the thermal range of energy, the effective cross-section for nuclear fission (see Section 1.3.4) is very large. For this reason, thermal reactors can be operated with a relatively small content of fissile material (lightly enriched uranium or natural uranium). The required enrichment depends primarily on neutron absorption in the moderator, coolant and structural materials, and also the desired burnup.

Reactors that work with fast neutrons (fast breeder reactors) do not contain a moderator.

A fast breeder reactor is the only type of reactor that can generate more fissile material in the form of ^{239}Pu than it uses by neutron capture in ^{238}U, which is subsequently converted to ^{239}Pu. Because of these characteristics, the fast breeder reactor is of fundamental importance for the long-term supply of nuclear fuel. Only in these reactors is the *conversion rate* > 1 (see Section 1.3.8). The reason is that the neutron yield per neutron absorption in the fissile material increases with increasing neutron energy and is sufficiently large only in fast breeder reactors. Nevertheless, fast breeder reactors require a substantially higher content of fissile material in the fuel than thermal reactors (ca. 15 – 30 % compared with 3 – 4 % in a pressurized-water reactor), so the probability is sufficiently high that the fast neutrons generated during nuclear fission will initiate new fissions before they are slowed down by collisions with fuel and coolant nuclei. Only substances that have a low slowdown power or a low density, particularly liquid sodium or helium gas, can be used as coolants (for detailed description, see page 164 and Section 4.1.2).

2.4.1.2. Fuels

Uranium dioxide is used as fuel in most types of reactors. It possesses a high melting point (ca. 2750 °C), favorable burnup properties, and good compatibility with cladding materials and most coolants. Although *carbidic fuels* (UC and UC_2) clearly have a higher thermal conductivity (especially UC), they are not yet well researched and are incompatible with water (important if the cladding tubes are damaged). However, UC may be the fuel of the future for sodium-cooled fast breeder reactors (see Section 4.2.1). For graphite-moderated high-temperature reactors (see Section 3.2.3.1), a ^{232}Th – ^{233}U breeding process seems suitable for reasons of neutron physics and materials science. Here, uranium dioxide (UO_2) is employed together with thorium dioxide (ThO_2) (in the future, possibly UC_2 and ThC_2) in the form of small particles that are coated with pyrocarbon and embedded in a graphite matrix. The ^{233}U, is bred from ^{232}Th which, with increasing burnup, steadily assumes the function of the fissile material.

Metallic uranium permits only low fuel temperatures and low burnup, and is used exclusively in Magnox reactors (see also Section 3.2.2.1).

2.4.1.3. Moderators

Only substances with a low mass number (good decelerating power) and a low neutron absorption can be used as moderators. Hence, H_2O, D_2O, and graphite are good moderators. *Heavy water* (D_2O) is contained in natural water to the extent of 0.015 % and is very expensive in the pure state (99.75 %), ca. $ 500 per kilogram (for methods of separation, see → Isotopes, Natural, Chap. 4.2.1.). D_2O also has a poorer slowing-down power than H_2O. For this reason, the volume required is higher by about an order of magnitude. Thus, D_2O-moderated reactors require moderator – fuel volume ratios of about 20: 1 and are, consequently, much larger than H_2O-moderated reactors with the same output. On the other hand D_2O has a lower (desirable) capture cross-section for neutrons than H_2O. That is why D_2O-moderated reactors can be operated with natural uranium (0.72 % ^{235}U). The same applies to *graphite*. Enriched fuel is, however, used in graphite-moderated advanced gas-cooled reactors (AGR) and in high-temperature reactors (HTR) to achieve a higher burnup.

2.4.1.4. Coolants

Coolants must have a high specific heat capacity, high density, good thermal conductivity, low viscosity, low susceptibility to activation, and low neutron absorption. In addition, they must be chemically compatible with materials and fuels. From the standpoint of heat transfer, the most important factor is the heat-transfer coefficient α of the coolant which, in turn, depends on the Reynolds number *Re* and the Prandtl number *Pr*, via the thermal conductivity λ_c, the hydraulic cooling- channel diameter D_h, and the Nusselt number *Nu*:

$$\alpha = \frac{\lambda_c \cdot Nu}{D_h}$$

$$Nu = f\ (Re, Pr)$$

$$Re = \frac{\varrho_c \cdot v_c \cdot D_h}{\eta_c}$$

$$Pr = \frac{c_{p,c} \cdot \eta_c}{\lambda_c}$$

where ϱ_c is the density, v_c the flow rate, η_c the viscosity, and $c_{p,c}$ the specific heat capacity of the coolant. For most coolants,

$$Nu \sim (Re)^{0.8}\ ;\ \alpha \sim \lambda_c \cdot \frac{(\varrho_c \cdot v_c)^{0.8}}{\eta_c}$$

The following proportionality applies to the ratio of the circulation power P_p (pump or blower power) to the thermal reactor power P_{th} [42]:

$$\frac{P_p}{P_{th}} \sim \frac{v_c^2}{c_{p,c} \cdot \Delta T_c} \sim \frac{(q'')^2}{\varrho_c^2 \cdot c_{p,c}^3 \cdot \Delta T_c^3}$$

where ΔT_c is the coolant warm-up span in the reactor (i.e., the difference between the outlet temperature $T_{o,c}$ and the inlet temperature $T_{i,c}$) and q'' is the heat flux density on the surface of the fuel rod.

Large heat-transfer coefficients α require large mass flow densities $\varrho_c \cdot v_c$, whereas large flow rates v_c result in large circulation power P_p. In gas-cooled reactors, the coolant circulation power P_p is acceptable only if the coolant heat-up span $\Delta T_c = T_{o,c} - T_{i,c}$ is large. Because the average coolant temperature $(T_{o,c} + T_{i,c})/2$ is particularly significant for the thermal efficiency of the plant, a loss of efficiency is acceptable here if the outlet temperature is limited by the construction materials used and $T_{i,c}$ must be lowered. In addition to the warm-up span ΔT_c, the combined data of the cooling medium $\varrho_c^2 \cdot c_{p,c}^3$ are particularly important for the relative circulation power P_p/P_{th}.

The thermohydraulic data of four typical power reactors are presented in Table 10. Practically, only water, heavy water, carbon dioxide, helium, and sodium are employed as coolants. In addition, organic liquids (disadvantage: radiation sensitivity), argon ($\varrho_c^2 \cdot c_{p,c}^3$ value is less favorable than that of He), and NaK (a eutectic alloy of approximately 20 % Na and 80 % K) were considered.

Water and heavy water are used both as coolants and as moderators. As a result of the low density of gaseous coolants and of the high mass number of sodium, an additional moderator (generally graphite) is necessary in these cases, allowing the reactor to operate with fast neutrons.

2.4.2. Reactor Types

The various moderators, coolants, and fuels could theoretically be combined to give a large number of different types of reactors. However, only the reactors described below have or had practical importance. Some technical data for typical power reactors are listed in Table 11. Details are given in the specific sections.

2.4.2.1. Light-Water Reactors (LWR)

Pressurized-Water Reactor (PWR). Water under high pressure serves as moderator and coolant, and lightly enriched uranium dioxide in cladding tubes made of zircaloy is used as fuel. The heat created in the reactor is transferred via a closed primary loop, with the help of steam generators, to a nonradioactive secondary cycle (see Fig. 10 and Table 11).

Boiling-Water Reactor (BWR). The boiling-water reactor is also moderated and cooled with water, but it differs from the pressurized-water reactor in that the water in the reactor is boiling and the resulting steam is led directly into the turbine without an interconnecting steam generator. This results in a simplified coolant circuit; the large steam generators and the pressurizer are no longer required, and the circulation power is smaller. The reactor operating pressure is lower than in pressurized-water reactors at about the same operating temperature. However, the entire circulation system is more or less radioactive. The reactor core has a similar design as that of a pressurized-water reactor, but the power densities attainable are lower. Also, more space for steam separators, etc., is required in the pressure vessel, which makes the pressure vessels of boiling-water reactors larger and more expensive than those of

pressurized-water reactors. Altogether, the advantages and disadvantages more or less balance each other, so that the pressurized-water reactor and the boiling-water reactor are the dominating reactor types (see Fig. 11, Table 11, and Section 3.1.2).

2.4.2.2. Graphite-Moderated Reactors

Graphite differs from water, from the point of view of neutron physics, in that it has a lower neutron absorption (desirable) but a poorer neutron moderation. For this reason, graphite-moderated reactors require substantially more moderator volume and are (for the same output) always much larger than water-moderated reactors. Basically, four different types of graphite-moderated reactors are used:

Magnox Reactors. Metallic uranium of natural isotopic composition in cladding tubes made of a magnesium alloy (Magnox) serves as the fuel. Carbon dioxide is employed as the coolant. The cooling channels pass through the graphite moderator. Fuel elements of this type allow only a low burnup and a low specific power (see Table 11). The costs of the plant are relatively high. Reactors of this type are no longer being built (see Section 3.2.2.1).

Advanced Gas-Cooled Reactors. In the AGR, metallic fuel rods are replaced by oxidic elements made of rod bundles (UO_2 pellets in cladding tubes of stainless steel) to improve the thermal and material properties. The fuel rods are similar to those used in H_2O- and D_2O-moderated reactors. Carbon dioxide is used as coolant. The use of steel as cladding material necessitates the use of slightly enriched uranium as fuel. The improvement in efficiency compared to the Magnox reactor is shown in Table 11. Until now, reactors of this type have been built only in the United Kingdom (see Section 3.2.2.2).

High-Temperature Reactors. The HTR is helium-cooled with fully ceramic fuel elements that are suitable for the highest coolant outlet temperatures (see Section 3.2.3). Helium is used as coolant because of its chemical inertness. Small particles of enriched uranium dioxide (or UO_2/ ThO_2 or UC_2/ ThC_2), about 1 mm in size, serve as fuel. These particles are coated with a protective layer of pyrocarbon and are embedded in block-shaped or spherical fuel elements made of graphite. The graphite acts as moderator

and, at the same time, transfers heat generated in the fuel to the coolant, which flows through the fuel elements in cooling channels (or around the spherical elements).

Reactors of this type are of long-term interest. Because of the high temperature of the heat produced, it can be used directly as process heat in chemical engineering (see Table 11). Furthermore, changeover from the normally employed water-steam turbine process (with heat exchanger) to the direct helium-gas turbine process is possible. The higher plant costs, compared with those of an H_2O-moderated reactor, as well as problems related to fuel production (see Section 5.3.2.2) and fuel reprocessing, are disadvantages of this reactor type.

Graphite-Moderated, Light-Water-Cooled Reactors (LWGR). The LWGR is built only in the former Soviet Union. The tubular fuel elements consist of a uranium – molybdenum alloy with approximately 3 % of ^{235}U enrichment. They are located in pressure tubes embedded in the graphite moderator. In more recent types, superheated steam is produced within the fuel elements (see Section 3.3).

2.4.2.3. Heavy-Water Reactors (D_2O – R)

The low neutron absorption of heavy water permits the use of natural uranium (0.72 % ^{235}U) instead of the enriched uranium (ca. 3 % ^{235}U) required for H_2O moderation. The expensive uranium enrichment process (→ Uranium, Uranium Alloys, and Uranium Compounds), which can only be carried out in special isotope separation plants (→ Isotopes, Natural), is avoided here. In contrast, substantially more D_2O than H_2O (similar to graphite-moderated reactors) is required for neutron moderation. For this reason, D_2O-moderated reactors are always considerably larger than H_2O-moderated reactors (with the same output). Plant costs are correspondingly higher.

Because much less heavy water is required for cooling purposes than for moderation, the fuel rods are not distributed evenly over the reactor (as in light-water reactors with their fuel elements directly adjacent to each other) but are accommodated as rod-bundle assemblies in individual cooling channels surrounded by D_2O. This functional separation of moderator (D_2O) and coolant allows the use of other coolants as well. Thus, in addition to D_2O, CO_2, H_2O, and organic liquids can be used as coolants, but in these cases, enriched uranium is generally required as fuel (for details, see Section 3.4).

2.4.2.4. Fast Breeder Reactors

Fast breeder reactors (see Table 11) contain no moderator and require fuel with a relatively high enrichment of fissile material (ca. 20 % ^{235}U or ^{239}Pu). The basic advantage of this type of reactor is that is "breeds" more fissile material in the form of ^{239}Pu from ^{238}U than it consumes (see Section 4.1.1).

The only coolant currently used is liquid sodium. In general, a nonactive sodium intermediate cycle is connected between the radioactive primary loop and the water – steam cycle for reasons of safety. Hence, the heat-transfer system is quite complex and the plant costs are high. At present, whether this disadvantage is compensated by correspondingly lower fuel costs is undetermined.

2.4.3. Future Developments

A prognosis for the development of various types of reactors is accompanied by substantial uncertainties. Over the next 15 to 20 years, *light-water reactors* are expected to dominate. Toward the end of this period, however, the high-temperature reactor and the fast breeder reactor could become important again. Regarding the ratio of pressurized-water reactors to boiling-water reactors, a shift in favor of the PWR can be observed (see Fig. 11). This may be due to some small economical and technical advantages of the pressurized-water reactor.

High-temperature reactors have suffered a few serious setbacks (all orders for commercial HTR nuclear power plants were withdrawn in 1975, and operation of the THTR-300 in Uentrop stopped in 1990). The reasons for this were technical plant problems, high plant costs, and unanswered questions regarding the fuel cycle. In view of the production of high-temperature process heat, of the possibility of a direct helium gas turbine process, and of its safety characteristics, the high-temperature reactor is without

competition and is therefore promising. This is confirmed not only by the great interest in this technology but also by the research efforts in some of the manufacturing countries.

Fast breeder reactors will probably become indispensable in the long term because of their breeding properties and because they are relatively insensitive to possibly dramatic increases in the price of uranium. The marketability of this type of reactor will depend essentially on the time when the price of uranium increases or when a possible shortage becomes apparent.

The D_2O-moderated natural uranium reactor is independent of enrichment plants and, for this reason, is expected to retain its market position, as shown in Figure 11, even in the future.

Research in the field of new reactor concepts includes both economic optimization of present reactors (better fuel utilization, recycling of plutonium, and lower plant costs by standardization) and further development of passive safety properties. The latter includes above all the guarantee of inherent automatic shutdown and residual heat removal. Very different concepts are being pursued in individual countries to achieve these goals. They are, however, all based on the principle of passive interruption of the chain reaction and removal of the residual heat via natural convection [45], [73].

Figure 15 shows the countries that use nuclear energy for peaceful purposes (as of January 1996) and the number and gross electric capacity of these reactors.

3. Thermal Reactors

3.1. Light-Water Reactors

Climatic changes are considered to pose a major impact on the environment. Thus the reduction of the emission of greenhouse gases from electricity generation units is in the focus of attention of energy planners, both at governmental and on utilities side. Nuclear power is one option to solve the current and future energy demand and to reduce the emission of greenhouse gases. Units fueled by renewable sources emit 2 – 5 times and those fueled by fossil fuels 40 – 100 times more greenhouse gases than nuclear power plants. By the end of 1995 nuclear power plants generated ca. 17 % of the electric energy worldwide. The total number of nuclear power plants in operation worldwide was 437, 343 of which were light-water reactors. The two main types installed are the pressurized-water reactor (PWR) and the boiling-water reactor (BWR), the PWR dominate in number and power output. Many countries depend heavily on nuclear power for production of electric energy. In some countries nearly 80 % of the electric energy is produced using nuclear power.

A broad experience of operating nuclear power plants is available worldwide, resulting from ca. 7700 reactor years. These units have proven their viability as an reliable, economic, and safe energy source. The operating records show the high availability of these plants, 80 % availability and above became the normal standard. Nuclear power plants are not only operating in base-load mode, in many countries their excellent load-follow capability could be demonstrated, which is fully compatible with that of fossil-fired power plants.

The economic viability for a reactor of a certain size could be attained and is higher than that of conventional plants. The overall energy situation in many countries, the lack of financing, and the stagnant request for electrical power reduces the need for new plants drastically. Programs for installing new nuclear units really exist in India, Japan, the Republic of Korea, Russia, the People's Republic of China, Taiwan and maybe Turkey. In countries such as the United States several nuclear units will be shut down in the next decade. The probalitiy that extensive new nuclear programs will be launched in the future remains questionable.

Even with that background worldwide development programs for advanced reactors are launched to achieve improvements in the next generation of nuclear power plants. The technology and the design of future nuclear power plants will inevitably change to adopt new requirements and to implement the operating experience from current nuclear power plants. The main goals of that development are improvements in economy, reliability, and availability. The safety of nuclear power plants has already reached a very high standard, consequently the space left for further enhancement is rather limited. Nevertheless, the new plants have to be de-

signed to withstand severe accidents (also called beyond-design basis accidents).

The advanced designs can be divided into two different categories. The first type can be called "evolutionary design", these new plants represent descendants of current plant designs. These advanced concepts feature improvements and modifications that are based on operating experience or are aimed at adopting new technological achievements. The second category covers design concepts that incorporate significant departures from current designs and need more engineering efforts, probably including construction and operation of a prototype plant. This category may be named "developmental design". For the evolutionary designs the goals vary from concept to concept and may incorporate features such as:

1) Passive safety features
2) Precautions to cope with severe accidents and its consequences (core melt, hydrogen production, steam explosion, cooling of the melt in the reactor or reactor building, prevention of interactions between core melt with base mat concrete, etc.)
3) Better fuel utilization, increase of discharge burnup, optimization of fuel design, application of burnable absorbers, improvement of neutron economy, use of blanket fuel assemblies

A large variety of advanced reactors are under development and under licensing. Specific

codes and standards specifying the new requirements on top of the utility requirements established in the United States, Europe, Japan, and Korea constitute the basis for the new designs. The safety requirements will mostly correspond to those applied for current designs. The additional or modified safety features incorporated shall prevent and mitigate severe accidents. The further purpose of the utility requirements is to present a clear, complete statement of utilities desire for the next generation of nuclear power plants. Due to the deviations in codes, standards, rules, and regulations a group of European utilities agreed to establish a separate set of requirements for European conditions, which deviate from the EPRI Requirements reflecting the practice in the United States. This may lead to a certain harmonization between the participating European countries. The first joint project established between France and Germany accommodates these European Utility Requirements as a basis.

Table 12 presents an overview of the various concepts currently under development. These efforts enable the future application of nuclear energy on an economic basis together with conventional energy sources such as fossil-fired power plants, renewable sources, and maybe others such as solar energy.

Situation in Germany. In Germany, 19 LWR plants are in operation 1997, with a total capacity of 21 984 MW_e. These 19 plants comprise 13 PWRs and 6 BWRs, with capacities of 15 367 MW_e and 6 619 MW_e, respectively. The PWR has become the preferred reactor type for electricity generation in Germany.

Concurrent with the increase in number of nuclear power plants (NPPs) the need of standardization became evident. Siemens – KWU initiated in 1980, together with the German utilities, experts from the TüV, and the licensing authorities, the Konvoi concept. For a series of successive nuclear power plants, the procedure provided for uniform planning using identical software and hardware for all site-independent equipment. As a consequence, construction schedules and costs could be stabilized, and the construction time reduced. The Konvoi plants went into operation between three and seven months ahead of schedule. This generation of German PWRs already incorporated "advanced" technology achievements that comply with the development targets specified for many advanced or next generation PWR plant designs.

Based on the experience gained from the operation of the German PWRs, in particular with the Konvoi plants, and from the huge PWR program in France, the two countries have agreed upon a joint development program for a PWR called the European Pressurized Water Reactor (EPR) (see Section 3.1.5). This development project was started by Siemens, the French supplier Framatome, and their jointly owned company Nuclear Power International (NPI), together with the French utility Electricité de France (EdF) and a group of German utilities. The respective national authorities were also involved from the very beginning.

The German utilities and Siemens have launched a further project, the development of a 1000 MW_e BWR with passive safety systems. The intent of this project is to establish an advanced BWR design that is based on the experience gained from current BWRs while taking into account new safety requirements, to be available for the utilities as an alternative to the PWR. Traditional safety systems will largely be replaced by passive systems to permit simplification of systems and structures, in order to improve the economic viability.

The following description of the PWR-technology is based on the Konvoi, a four-loop 1300 MW_e PWR, contracted for three independent sites in Germany. Because of the various codes, standards, rules, and regulations applied in the different countries the technology

used and the safety approach also differ from country to country. The Russian technology of the WWER-plants compared to western PWRs demonstrates the huge differences between the plant designs. A detailed analysis of different designs would be beyond the scope of this contribution.

3.1.1. Pressurized-Water Reactors

In 1995, a total of 250 PWRs were in operation worldwide (see Table 13; including the Russian WWER) with a total capacity of 220 395 MW_e (≈ 64 % of the total nuclear capacity installed). In Germany the nuclear program consist of 19 LWR from which 13 NPP are of the PWR type. The German PWR design was developed by Siemens (KWU) in accordance with German requirements (see Section 3.1).

The following description of the PWR technology is based on the Konvoi, a four-loop 1300 MW_e PWR, contracted for three independent sites in Germany. Because of the various codes, standards, rules, and regulations applied in the different countries, the technology used and the safety approach also differ from country to country. The Russian technology of the WWWer plants compared to western PWRs demonstrates the huge differences between the plant designs. A detailed analysis of different designs would be beyond the scope of this contribution

3.1.1.1. Design [77]

The essential feature of pressurized-water reactors, as distinguished from boiling-water reactors, is the closed reactor coolant system that is separated from the secondary water – steam cycle. The demineralized water used in the reactor coolant system is maintained at a pressure of 15.7 MPa and an inlet temperature of 291.3 °C. Water is heated on flowing through the reactor core to an average outlet temperature of 326.1 °C. Because of the high pressure, the heat transferred from the fuel assemblies to the reactor coolant does not cause coolant evaporation in the reactor core. Depending on the capacity of the plant, the reactor coolant system may have two, three, or four identical loops, each consisting of a steam generator, a reactor coolant pump, and interconnecting piping between the components. A pressurizer is connected to one loop to regulate the pressure in the reactor coolant system. The pressurizer is partly filled with water, the balance being steam. During operation the pressure of the steam can be either raised by means of electrical heaters in the pressurizer bottom or lowered by injecting water through sprays in the head. Overpressures during transients are reduced by relief valves and safety valves, which blow steam down into the pressurizer relief tank. There, the steam condenses by direct contact with the water contained in the tank.

Figure 16 shows the isometric arrangement of the reactor coolant system in a four-loop PWR plant. PWR-Konvoi plants in Germany

are currently operating with a power output of 1450 MW_e. The next generation of advanced PWR plants, accommodates an electric power output of 1500 MW_e, which corresponds to a thermal reactor power of 4250 MW_{th}. To increase the economic viability of nuclear energy in comparsion to conventional power plants, these large units are favored. The increase in power is accepted by the licensing authorities because of the very conservative average linear heat rate. Various measures are incorporated in the new designs, i.e., fuel management procedures and advanced fuel assemblies which lead to higher discharge burnup of $\approx 60\,000$ MW · d/t.

Figure 16. Four-loop primary coolant system of a 1300-MW pressurized-water reactor
a) Reactor pressure vessel; b) Steam generator; c) Reactor coolant pump; d) Pressurizer; e) Pressurizer relief tank

If grid expansion is planned, the new units should not have a larger capacity than ca. 10 % of the total power installed. In addition, a redundancy for the new nuclear unit (i.e., a second nuclear power plant) of the same size should be planned to cover outages for maintenance and other nonavailability reasons. This strategy may limit the installation of large units. For these cases nuclear power plants with an output of 600 MW_e or 1000 MW_e are available. The plant size not only depends on economic aspects, also the forecast for the future energy market is essential. The development of the local industry and the dependency on only a single energy resource may promote the application of small and medium nuclear power plants.

In countries with a total grid capacity $< 15\,000 - 20\,000$ MW, larger units cannot be incorporated into the grid, especially, if only smaller conventional units exist as redundancies. For grid expansion planning it is essential to have sufficient redundancy available in case the larger nuclear unit is shut down for some reasons.

The thermal flow diagram of a 1300 – 1400-MW four-loop plant is shown in Figure 17; characteristic data are given in Table 14. The reactor coolant is heated in the reactor core (a) and transfers its heat in the steam generator (b) to the secondary-side feedwater, which is converted into steam. The saturated main steam thus produced passes at 70 MPa through the main steam line to the saturated steam turbine (f). After releasing its enthalpy content in the turbine, the exhaust steam condenses in the condenser (i). The condensate is pumped through the low-pressure heaters (k) into the feedwater tank (m). Feedwater pumps (n) transfer feedwater through the high-pressure heaters (o) to the secondary side of the steam generator. A moisture separator (g)/reheater (h) between the high-pressure and low-pressure sections of the turbine improves the efficiency of the plant. Furthermore, this vessel prevents droplet impact erosion damage to the low-pressure turbine.

Wall thickness, mm	38

Separation of the reactor coolant system from the water – steam cycle not only allows the secondary system to be kept free of radioactivity while in operation but, above all, permits independent selectivity of water chemistry and materials for the primary and secondary systems. High water purity is required on the primary side to ensure a low corrosion rate. On the secondary side, proper selection of materials, leaktight components such as the condenser, and correct water chemistry in accordance with the specification are important in preventing the transport of corrosion products into the secondary side of the steam generator.

Reactor Core. The reactor core, which is located in the reactor pressure vessel (RPV), is the heat source for the nuclear power plant. It comprises square fuel assemblies with a square cross-section, which are arranged in an approximately circular array in the RPV. The core of a 1300-MW pressurized-water reactor contains 193 fuel assemblies. The nuclear fuel is usually uranium dioxide with an equilibrium ^{235}U enrichment of 3.2 – 3.4 wt %. Mixed uranium – plutonium oxide (MOX) can be used instead of uranium dioxide. For long-term reactivity changes, the chain reaction is controlled by dissolution of boric acid in the coolant; for short-term changes, control assemblies are used. Gadolinium is incorporated in the fuel of the first core to compensate for a certain amount of excess reactivity so as to maintain a negative fuel temperature coefficient. Since the power density distribution over the cross-section of the first core, and subsequently that of the equilibrium core, should be as even as possible and because there is no burnup at first core, fuel assemblies with different enrichments (e.g., 1.9, 2.5, 3.2 wt % ^{235}U) are used (Fig. 18).

Thermal design of the core must ensure that no damage can occur to the fuel cladding during all feasible modes of operation of the plant. Furthermore, the prevention of film boiling is a critical variable (DNB ratio; see Section 2.2). A theoretical "hot channel" is defined to establish a minimum DNB ratio. In the definition of this channel, all phenomena are considered that increase local heat flux in the core above the average value. The core is then designed in such a way that the hot channel withstands every conceivable adverse operating condition. This design approach ensures a high safety standard, because all phenomena tending to increase heat flux in the core are extremely unlikely to occur at the same place at the same time. Another crucial physical variable with respect to economic operation is the average fuel assembly burnup (i.e., the average total energy generated per unit mass). Today's modern pressurized-water reactors can achieve discharge burnups of 45 000 – 50 000 MW · d per tonne of uranium within 3 to 4 years of operation.

Fuel Assemblies. For fuel fabrication, powdered UO_2 is pressed into *pellets* of ca. 10 mm in height and diameter. The pellets are then sintered and filled into ca. 4-m long cladding tubes. The *fuel rods* thus formed are pressurized to approximately 2.0 MPa to reduce the mechanical loading during operation and then sealed gastight with an end cap (for details on fuel fabrication, see Section 5.3.1). A number of fuel rods are bundled together to form fuel assemblies; the quantity of fuel rods depends on the power output of the reactor. A square bundle containing 14×14 to 18×18 fuel rods is generally used today. The bundle is open on all sides and forms a structural unit with the control assembly.

The *fuel-assembly structure* consists of several spacer grids that are welded to the control rod guide thimbles at regular intervals between the top and bottom end fittings. The fuel rods are held elastically in this skeleton and are free to expand and contract axially. Mixing vanes on the spacers prevent laminar flow and local superheating at the cladding. They equalize heating of the coolant in its passage through the reactor core, and a high power density can be achieved without approaching critical states. The *first core* configuration is zoned with differently enriched fuel assemblies to attain as broad a peak power distribution (flat Gaussian distribution) as possible. *Reload fuel assemblies* have a uniform enrichment which depend on the length of the fuel cycle (e.g., 3.2 or 3.4 % ^{235}U)

Absorber rods located in the control rod guide thimbles in the fuel-assembly structure are bundled to form *control assemblies*. Each of these is moved up and down by an electromagnetic jack mechanism on the head of the reactor pressure vessel.

Components of the Reactor Coolant System. The *reactor pressure vessel* (Fig. 19) with its internals accommodates the reactor core and channels the coolant. The coolant enters the vessel through the inlet nozzle (d), flows downward through the annular gap between the core barrel (j) and the pressure vessel wall (i), is reversed in the bottom head and flows upward through the reactor core, leaving the vessel through the outlet nozzle without further contact with the wall of the pressure vessel. The coolant inlet and outlet nozzles are the only penetration through the

Figure 20. Steam generator
a) Steam dryer; b) Moisture separator; c) Tube spacer grids; d) Heating tube bundle; e) Tube sheet; f) Support

wall in the body of the RPV. Thus, refilling of the reactor core by the emergency core cooling and residual heat removal systems is ensured under all circumstances, even in the event of a reactor coolant pipe rupture. No penetrations are located in the lower part of the vessel, thus no breakage must be considered.

The RPV is the central fixed point of the nuclear steam supply system. Support lugs and horizontal stops that are welded to the shell flange transfer the load of the vessel to the building structure. The latter is designed to absorb all forces and moments during operation and hypothetical accident conditions.

The pressure vessel is made of seamless forged rings. It has a spherical bottom head and a flange ring at the top. This forged flange ring accommodates the coolant nozzles and forms the mating flange for the RPV head. A flange ring and a dome plate are welded together to form the pressure vessel head. This dome plate contains the nozzles for the control assemblies and the in-core instrumentation. Concentric, metal O-rings are used to seal the flange surfaces of the head and body of the reactor pressure vessel; 52 necked down studs hold the two parts together. The studs are uniformly preloaded with a hydraulic or electrical stud tensioner. The base material for the RPV walls is 20 MnMoNi55 steel, which contains a welded two-layer austenitic strip corrosion-resistant cladding. The vessel is surrounded on the outside by self-supporting thermal insulation, which provides unrestricted access from the outside for later in-service inspection. The insulation around the head flange is removable.

The *core structure*, the basic structural framework of the reactor core, consists of (1) the lower core structure and (2) the upper core structure with control rod guide assemblies (b).

The core structure has the following functions:

1) Taking the weight and restraint forces of the fuel assemblies
2) Alignment and location of the fuel and control assemblies
3) Accommodation of the thrust of the control assemblies on the reactor trip
4) Distribution of the reactor coolant flow
5) Support of in-core instrumentation
6) Reduction of the neutron irradiation of the pressure vessel wall
7) Accommodation of irradiation specimen for accelerated monitoring of the properties of the pressure vessel material

The core structure is built in such a way that it can be removed as a whole from the reactor pressure vessel. The upper core structure is removed during refueling. The upper core structure, or even the complete core structure, can be stored in a designated setdown area in the reactor well.

The *lower core structure* consists of the cylindrical core barrel (j). The core barrel houses the polygonal core shroud that surrounds the core.

The lower core structure is closed at the bottom by the lower core support (k) and the flow distribution plate. The core barrel, centered by shims, is suspended from the ledge on the pressure vessel flange. The part of the barrel shell around the core belt line serves simultaneously as a thermal shield. Lateral stops limit radial displacement.

The lower core support (k) is the actual support structure and is integrated into the lower section of the core barrel. The flow distribution plate, together with the flow skirt (l), provides uniform coolant flow through the reactor core.

Irradiation channels for the housing of irradiation specimens for accelerated monitoring of the properties of the RPV material are fastened to the outer wall of the core barrel close to the outlet nozzle.

The *upper core structure* is located in the nozzle section of the core barrel and thus closes the reactor core at the top. It consists of the upper core support and top plate, support columns, control rod guide assemblies (b), and the grid plate (c). The core barrel and the upper core structure are held by hold-down assemblies with Belleville springs between the flanges of the reactor pressure vessel.

On refueling, the upper core structure is removed, together with the disconnected control assembly drive rods (a), with the aid of a lift rig from the flooded pressure vessel. Guide rods in the pressure vessel and centering pins on the core barrel ensure proper alignment during the lifting process. The height of the upper core structure is largely determined by the length of the control assemblies because these are almost completely withdrawn from the core during operation. Austenitic materials are used exclusively for the core internals.

The heat released in the reactor core is transferred by the *steam generator* (Fig. 20) from the reactor coolant to the feedwater – steam cycle. Thus, the steam generator forms the barrier between the radioactive and nonradioactive cycles. It is a vertical U-tube heat exchanger with natural circulation on the secondary side. The reactor coolant enters the hemispherical primary channel head through the inlet nozzle, flows through the ca. 4000 U-tubes where it releases its heat content and then leaves the steam generator through the outlet nozzle.

Feedwater enters the steam generator through an inlet nozzle in the steam dome and is distributed uniformly around the circumference by a sparger ring arranged around the cylindrical tube shroud. The feedwater mixes with the water returned from the moisture separator (b) passes into the downcomer, and from there flows radially into the tube bundle above the tube sheet. An annular flow restrictor in the downcomer produces the pressure drop required for stable natural circulation in the single-phase regime. The steam – water mixture above the tube bundle passes through the moisture separator (b) and steam dryer (a). The water separated from the steam then flows back into the downcomer and mixes with the freshly supplied feedwater. The recirculation coefficient (the ratio of the recirculation mass flow to feedwater mass flow) is ca. 4. Dried steam exits through the outlet nozzle in the steam dome and flows to the turbine along the main steam line.

To attain maximum leaktightness, the steam generator tubes are not only welded to the primary-side cladding but also tightly rolled into the tube sheet. The walls of the vessel are made of 20MnMoNi55X forged steel; material 1.4858 (similar to Incoloy 800) is used for the heat-exchange tubes. This material is especially re-

sistant to intergranular and transgranular stress corrosion cracking.

Flow through the reactor coolant system occurs by forced circulation. One *reactor coolant pump* (Fig. 21) is installed in each loop to overcome pressure losses in the reactor pressure vessel, the steam generator, and the connecting piping.

Figure 21. Reactor coolant pump with integrated oil supply a) Motor flange; b) Oil cooler; c) Shaft coupling; d) Standstill seal; e) Hydrodynamic shaft seal (three-stage); f) Pump casing; g) Lantern; h) Radial bearing; i) Axial bearing; j) Diffuser; k) Impeller

A three-stage hydrodynamic shaft seal (e) prevents uncontrolled leakages from the primary system to the reactor building. The system pressure in the pump casing is reduced to atmospheric pressure by this three-stage hydrodynamic shaft seal. Purified barrier water is the medium used for the hydrodynamic seals. The high-pressure leak-off is discharged into the volume control system, and the low pressure leak-off is passed into the equipment drain system.

If all three seal stages fail at the same time, a separate standstill seal (d) is inserted by nitrogen pressure. This seal is able to withstand the full system pressure. Extensive instrumentation is provided for controlling the pump units in operation. The electrical data of the motor, the temperatures and pressures in the bearings and seals, and, lubricating oil and leak-off flows are constantly monitored.

The *pressurizer* (Fig. 22) builds up the pressure required for operation of the reactor coolant system. It also limits and compensates for coolant volume fluctuations without causing substantial pressure changes. Fluctuations in coolant volume occur because of changes in system temperature following load changes. The pressurizer is partly filled with boiling water with a steam cushion above.

Figure 22. A) Pressurizer; B) Pressurizer relief tank
a) Vent nozzle; b) Central spray nozzle; c) Box-type spray manifold and spray nozzles; d) Nozzle for safety and relief valves; e) Instrumentation nozzle; f) Manhole; g) Spray skirt; h) Surge line nozzle; i) Instrumentation nozzle; j) Heater rods; k) Steam dome; l) Rupture diaphragm

Electric heaters, spray nozzles, and a pressure relief system are used for pressure control. When the pressure drops, the electric heater (j) is switched on so that water evaporates and the pressure returns to its set point. When the pres-

sure rises, either plenum water is sprayed into the steam space to condense steam, or the relief valves (d) are opened to discharge steam, thus lowering the pressure to its set point. The changes in pressure in the reactor coolant system are communicated to the pressurizer by the surge line (h). The steam blown down by the relief valves is condensed in a body of water in the pressurizer relief tank (B) which is connected to the pressurizer. This vessel is not exposed to the reactor coolant system pressure it is kept at a low pressure.

Reactor Building. (Fig. 23) The reactor building contains the reactor system, all other high-pressure and fuel handling systems, parts of the safety systems, ventilation systems, and instrumentation. The entire building is part of the controlled area. The reactor building is a double containment structure that consists of an inner, free-standing steel sphere (the containment proper) surrounded by a concrete shell that provides secondary shielding. The space between the steel sphere and the concrete shell, the *annulus*, accommodates (1) the emergency core cooling and residual heat removal systems, (2) the component cooling systems, (3) the extraborating system, and (4) the high-pressure pumps of the volume control system. With a wall thickness of ca. 2.00 m, the concrete building is designed to withstand airplane crashes, earthquakes, sabotage, gas explosions, flooding, and the radiological loading produced during a design basis accident.

The *containment interior* is divided into service and equipment compartments. The latter are separated from the steel containment by the missile shield (i). A distinction is made between compartments that are and those that are not accessible at any time during operation. The plant compartment is maintained at a slightly subatmospheric pressure compared to the service compartments. These compartments are separated by an airtight seal. Thus, if leakages occur in systems, no radioactivity can escape into the accessible compartments. Four airlocks lead into the containment interior, i.e., the normal personnel airlock connecting the auxiliary building with the service compartments, two emergency airlocks, and an equipment airlock (j). The gantry crane that is used to transport shipping casks for new and spent fuel assemblies into and out of the building is located outside the equipment airlock. The spherical geometry provides sufficient space on the service level for the storage of refueling equipment and for maintenance and repairs, as necessary.

If the design basis accident occurred, pressure equalization ports would equalize the pressures in the equipment and the service compartments. The concrete walls are dimensioned to withstand a certain pressure difference and the jet impingement forces that would occur. The full-pressure containment vessel is designed for ca. 0.53 MPa and 145 °C, i.e., the conditions calculated for a design basis accident. Additionally, a containment venting system consisting of relief valve, filter, piping, and controls is provided to protect the containment in the highly improbable event of a core melt accident.

Reactor Auxiliary and Supporting Systems. Trouble-free operation of the reactor coolant system is not possible without a variety of auxiliary and supporting systems. Besides fulfilling the requirements associated with plant operation (e.g., supply, purification and treatment of coolant), some of these systems are essential to meet the stringent requirements pertaining to the internal and external safety of the overall plant and to environmental protection. The important criteria for design of the auxiliary and supporting systems are dictated by the reactor coolant system; together they all form the nuclear steam supply system.

In particular, the *emergency core cooling and residual heat removal system*, which ensures cooling of the core when the reactor is shut down and in the event of loss- of- coolant accidents, is important for plant safety. The *volume control system* is the link between the hot, high-pressure reactor coolant system and the low-pressure systems of the reactor auxiliary systems. It interacts with the pressurizer to equalize fluctuations in coolant volume caused by temperature and operational changes, and with the *chemical control system* to adjust the coolant chemistry to specified levels. To maintain high water purity, the volume control system continually releases a part-flow of the coolant circulating in the reactor, conveys it to the *coolant purification system* for removal of fission and corrosion products, and subsequently feeds it back into the reactor coolant system. Various *processing systems* pro-

tect the environment by ensuring that gaseous, liquid, and solid radioactive releases are kept below stipulated limits.

3.1.1.2. Instrumentation and Control [78], [79]

Instrumentation and control (I & C) functions in nuclear power plants include measurement, control, regulation, monitoring, and protection. The operational functions of the overall plant are based on the physical, chemical, process engineering, and operational requirements placed on the systems and plant equipment. The instrumentation and control system can be subdivided into safety and operational I & C. Plant and environmental protection are assigned to the safety systems. These systems operate predominantly on demand, and most are inactive during normal, trouble-free operation. The operability of this redundantly structured system is continually checked by self-monitoring and periodic function testing. The reactor power controls are usually considered to be part of the safety I & C. The operational I & C includes all systems that ensure trouble-free normal operation of the nuclear power plant and has a decentralized and hierarchical structure. That is why it can be divided into functional groups and complexes in line with the process functions.

Safety I & C. Safety instrumentation and control are shown in Figure 24 and [80].

Reactor Control. The function of the reactor power controls is to match reactor power to the generator output demand at any time. This is carried out by measuring relevant control variables, such as neutron flux, power density, and coolant temperature. The reactor power controls also regulate pressures, water levels (in, e.g., steam generator, pressurizer), flow rates, and temperatures.

The *generator load controller* controls steam extraction by the turbines in accordance with the power demand of the electric grid. Reac-

Figure 24. Safety instrumentation and control

tor power controls use the self-regulation of the reactor to match its power to generator output. An increase in steam extraction causes a gradual decrease of coolant temperature in the steam generators. Because of the negative temperature coefficient of the reactor reactivity, which sets in after a certain period in service, the output of the reactor increases. Thus, part of the increased steam demand of the turbine is automatically met. This process is reversed when turbine load is reduced.

The *reactor power controls* immediately intervene in the case of large and rapid load changes in the reactor plant. Two modes of control are possible:

1) Operation at constant main steam pressure. For the water – steam cycle, this has the advantage of a reduction in design pressure and turbine throttling at partial load.
2) Operation at constant average coolant temperature. This is the reactor-oriented mode (small control rod movements because of no additional feedback effect on the steady-state coolant temperature when load is changed; largely constant water level in the pressurizer because of only small changes in coolant volume; possibility of heat storage in the steam generators at partial load because pressure increases with decreasing load).

As shown in the part load diagram (Fig. 25), the Konvoi plants use a combination of the two modes.

In addition to these considerations, the reduction of thermal loadings on the reactor pressure vessel in the normal output range of 50 – 100 % is crucial to the life expectancy of the plant.

Reactor power is controlled by neutron absorbers. Control assemblies variously grouped in banks effect rapid changes in reactivity. Slow changes (such as compensation of xenon buildup and burnup) are achieved by altering the concentration of the boric acid dissolved in the coolant by adding either boric acid or demineralized water. As mentioned in Section 3.1.1.1, addition of gadolinium to the fuel compensates for the initial excess reactivity present in the first core. Gadolinium is burned up in the first operating cycle and removed from the core with the spent fuel assemblies during the first refueling outage.

Reactor Protection. The task of the reactor protection system is to reliably detect all design basis accidents and to initiate highly reliable protective actions that ensure the safety of the plant at any time. Accidents are sequences of events dictating that plant operation must be discontinued for safety reasons. An analog data acquisition system detects accident-specific process variables, and logic gating circuits generate actuation signals when certain limits are exceeded. These actuation signals initiate reactor trip and, taking priority over all operational controls, activate engineered safety features required for accident control. In all cases, accident detection is based on different (diverse) process variables to eliminate uncertainties in the accident detection system and common-mode failures in the data acquisition system. Redundancy is provided to mitigate the effects of initiating events within the reactor protection system. Individual redun-

dancies are physically and spatially separated and are accommodated in buildings designed to withstand external events. The reactor protection system panel gives operating personnel an overview of the state of the reactor protection system at all times during normal operation and accident conditions. Periodic testing is performed by means of special testing equipment. Active and passive failures in the initiation channels are self-reporting.

Reactor Limitation Functions. In the event of deviation of process variables from their set points that cannot be corrected by the controls, limitation systems trigger certain countermeasures. The latter usually make shutdown unnecessary so that the plant can stay in operation. These limitation systems also include the core protection system and act in tandem with the controls and the reactor protection system to provide extensive safeguards for the I & C system and to increase the safety and availability of the plant.

Radiological Protection and Monitoring [81]. The function of radiological protection is to keep radiation exposure and contamination in the nuclear power plant and the environment as low as possible. The radiation monitoring system measures and records radiation in the various controlled areas. Different radiation monitoring systems are provided to survey local dose rates, systems, and areas, the environment and personal doses, as well as the release of solid, gaseous, and liquid wastes. The monitoring systems include permanently installed instruments that are integrated into the I & C system; stationary monitors (e.g., contamination monitors), which indicate locally, continuous, and intermittent sampling points; and mobile radiation measuring instruments for local or personal monitoring. The samples are evaluated in the health physics laboratory. Table 15 shows the number of permanently installed radiation monitors in a Konvoi plant.

Figure 26. Tasks of the operational instrumentation and control

Neutron Flux Measurement. The neutron flux inside and outside the core is measured to detect the reactor power and power density distribution. *Outside the reactor pressure vessel*, the source, intermediate, and power range channels are installed, which measure the integral reactor power in ionization chambers over approximately 13 decades. The measured data are used for indication, display, control, limitation, and protection, as well as the process computer.

In the reactor core, 48 self-powered detectors measure the power density. The Aeroball system is used for calibration of neutron-flux instrumentation channels and for intermittent neutron-flux mapping. In the reactor core, stacks of vanadium alloy steel balls (diameter 1 mm) are activated by the neutron flux. The activation measurements are transmitted to a computer connected to the Aeroball system which calculates the relative power density distribution in the core and references it to the thermal output.

Operational Instrumentation and Control (Fig. 26). The operational instrumentation measures the various physical, mechanical, and chemical process data and converts measured data into electrical signals. These binary and analog signals are used for control, regulating, and monitoring functions. The normal trouble-free operation of a nuclear power plant is performed by the operational instrumentation and controls.

Manual operation and observation of the overall nuclear power plant process takes place in the central control room. The control room is divided into the master control station and the systems control boards, on which the control tiles, monitors, printers, alarms, and display units are arranged.

Konvoi plants are additionally equipped with the computer-aided process information system PRISCA. This is a problem-oriented decentralized data acquisition computer. The classical tasks of a supervisory computer, such as recording process events on paper, indicating alarms on video display units, and performing nuclear calculations, are supplemented by the processing of high-grade process information and the output of process graphics on color CRT (cathode-ray tube) monitors. Thus, the functions of all systems can be observed during normal operation and accidents; the fulfillment of important safety functions can be monitored and the effectiveness of automatic and manual actions can be controlled.

Further developmental trends in operational I & C are toward programmable and redundant automation systems interconnected by local area networks.

3.1.1.3. Nuclear Power Plant Operation

The operation of a reactor is divided into three phases, start-up, load operation, and shutdown. A typical *start-up* diagram of a pressurized water reactor is shown in Figure 27. When the plant is started up from the cold condition, it is first vented and then pressurized to approximately 3.5 MPa by heating the pressurizer. Subsequently, the reactor coolant pumps start up. The reactor is made critical by control rod withdrawal and deboration of the coolant. Then it is warmed up at a rate of about 50 K/h by nuclear heat generation. The reactor is capable of delivering power to the turbine 4 h after reaching criticality and about 13 h after start-up.

Figure 27. Start-up diagram
a) Pressurizer heaters switched on; b) Reactor coolant pumps started; c) Reactor goes critical

In *load operation* the interactive controls for generator output and the reactor coolant temperature implement load changes ranging from 30 to 100 % nominal load at rates of up to 10 %/min (relative to nominal load) within wide margins about the starting point. The entire load range can be traversed in about 60 min. The stored energy capacity of the steam generators is used for rapid load changes. Hence, pressurized-water reactors are suitable not only for base-load operation but also for load cycling because of their self-regulation features.

After about a year of full-load operation, the core approaches the end of its cycle because all excess reactivity has been burned up. This state is reached when the full power can no longer be maintained even if the control assemblies are almost completely withdrawn from the core. However, the cycle duration of the core can be extended by slightly reducing the coolant temperature and limiting the power output (stretch-out operation). This permits the plant to operate for another 60 – 100 d before output falls below 70 or 50 %. The output averaged over this period is 85 % and 75 %, respectively. Thus, the time at which the reactor is shut down for refueling can be coordinated with operational requirements.

The *shutdown* process is shown in Figure 28. First, the plant output is reduced to 30 % by manually adjusting the generator load set point. The coolant temperature control follows automatically. The output is then further reduced to 15 % by lowering the neutron-flux set point (also manually). At first, the reactor is cooled by the steam generators and the main steam bypass station (steam dumping into the condenser) until the temperature has been decreased sufficiently (≈ 120 °C). Then cooling is taken over by the residual heat removal system.

Figure 28. Shutdown diagram
a) Reactor coolant pumps tripped; b) Residual heat removal system in operation; c) Spraying from value control system

3.1.1.4. Radioactive Releases to the Environment

Operational experience with pressurized-water reactor power plants has shown that they emit only very small amounts of radioactivity during operation. As a result of their design (highly efficient processing and retention systems for liquid and gaseous effluents, shielding) and intensive personnel training, the average emissions are far below the statutory limits. The actual levels for individual plants depend on a variety of factors, such as height of stack, method of processing, weather conditions, mode of operation–base load or load cycling–and fuel quality. In a modern 1300-MW plant, *gaseous emissions* from the stack are generally $< 3.7 \times 10^{13}$ Bq/a (predominantly noble gases ^{133}Xe, ^{41}Ar, ^{85}Kr, traces of ^{131}I, and aerosols). The activity of annual *liquid effluent* releases is limited to ca. 3.7×10^{10} Bq/a but actual values are usually less. In addition, a particular feature of pressurized water reactors is that tritium emissions are 2.2×10^{13} Bq/a averaged over a period of several years. However, this is only of secondary importance because the radiotoxicity of tritium is low compared to other isotopes. These emission levels raise the radiation background in the plant environment by 0.5 Sv/a, which is less than 1 % of the radiation emitted by natural sources. Up to now, not one case of radiationinduced impairment of health is known to have occurred in the vicinity of a PWR nuclear power plant.

Annual emissions of radioactive substances in becquerels, from a 1300-MW plant may be summarized as follows:

Gaseous effluents	
Noble gases	4×10^{12}
Aerosols	1×10^{7}
^{131}I	5×10^{6}
Liquid effluents	
Fission and activation products (without tritium)	2.2×10^{9}
Tritium	1×10^{13}

However, these values depend very strongly on individual plant parameters. A comparison of older data with those of recent years reveals that constant efforts are being made to reduce the radiation exposure of both plant personnel and the environment at large.

3.1.1.5. European Pressurized-Water Reactor

The European Pressurized-Water Reactor (EPR) is currently being developed by Nuclear Power International (NPI) and its parent companies, Framatome and Siemens, in cooperation with EdF and German utilities, aiming at achieving a new improved nuclear power plant design that will become an acceptable and attractive alternative for meeting energy demands in the future.

3.1.1.5.1. Description of the Nuclear Systems

Primary Circuit and its Main Characteristics. The primary loop configuration is the same as that of existing designs and can be considered well-proven. The reactor pressure vessel (RPV), steam generator (SG) (especially secondary side) and pressurizer (PZR) are of a larger size than current designs.

In the *reactor pressure vessel* the free water volume between the level of the reactor coolant lines and the top of the active core is increased in order to improve the mitigation of loss of coolant accidents (LOCA) by prolonging the period until beginning of core uncovery in case of LOCA or minimizing the depth of core uncovery, if any. At the same time the increase of this volume contributes to an improvement in the mitigation of accidents at shutdown conditions (in particular mid-loop operation), e.g., with loss of the residual heat removal system (RHR), by providing longer grace periods.

For the *pressurizer* a large volume both in terms of water and steam phase is provided in order to smoothen plant response to relevant operating transients and accidents. The great water volume of the secondary side of the *steam generator* supports smoothing of normal operating transients and reduces the potential for unplanned reactor trips. In case of a total loss of all feedwater supply (including emergency feedwater), the expected dryout time of the SG will be > 30 min. The valve configuration of the primary side overpressure protection aims at avoiding the response of "nonisolatable valves" in plant conditions with a potential for radioactivity release. The valves are mounted to the top of the pressurizer in order to minimize the length

of high pressure piping. Each of the three discharge trains is provided with two safety valves. Automatic opening of the main valve is actuated by pilot actuators dedicated to each individual safety valve.

With the chosen arrangement of pressurizer discharge, the following safety functions can be performed:

1) Overpressure protection of the reactor cooling system by automatically initated discharge of either steam, water or two-phase fluid
2) Depressurization of the reactor cooling system by discharge of steam, water or two-phase fluid in plant conditions when pressurizer spraying is not available or not efficient
3) Discharge of the reactor cooling system to enable residual heat removal in case of unavailablility of the secondary side heat removal (feed and bleed)
4) Discharge of the reactor cooling system in a postulated core melt situation to guarantee depressurization to a sufficiently low level that would rule out the high pressure core melt accident and its severe consequences.

On the secondary side of the SGs, three discharge trains will be arranged on each main steam line at the outlet of the containment. One discharge line will be equipped with a relief valve (normally open) and an isolation valve (normally closed). The two other discharge lines will be equipped with nonisolatable safety valves.

Reactor Core and Fuel Design. The reactor core is built up by 241 mechanically identically designed fuel assemblies; somewhat more than in currently operating units. Each fuel assembly consists of 264 fuel rods and 25 guide tubes arranged in a 17×17 array; their active length is 4.20 m. The fuel rods are made of Zircaloy tubing containing uranium dioxide ceramic pellets (initial enrichment ≤ 5.0 wt %). The core is designed for UO_2 fuel elements. They can be substituted up to about 50 % by MOX fuel assemblies. Some fuel assemblies contain burnable absorber (Gd_2O_3) to suppress high excess reactivity, especially in the first core. The reactor power level is monitored by the ex-core instrumentation. The in-core instrumentation consists of the aeroball system and the self-powered detector system which controls the power distribution in the core. The in-core instrumentation penetrates the reactor pressure vessel head from the top at only very few positions.

Primary Components. The *reactor pressure* vessel is designed for a lifetime of 60 a. A total neutron fluence of 10^{19} *nvt* will not be exceeded. This is achieved by provision of a rather large water gap and a heavy reflector around the core. The upper part of the reactor pressure vessel will be machined from one single forging. The flange is made as an integral part of the nozzle shell. The nozzles themselves are of the on-set type so that nondestructive examination can be easily performed from the inside. The nozzles are located as high as practicable above the upper edge of the core to increase the hydrostatic pressure for reflooding and to avoid the loop seal effect. The reactor pressure vessel is internally clad with two layers of low-carbon stainless steel. Generally, in-service inspection is performed from inside the vessel; an access from the outside, between the outer wall and the thermal insulation, is also provided.

Reactor Internals. The core barrel flange rests on a ledge machined from the flange of the reactor pressure vessel and is preloaded by an elastic system. The fuel assemblies are placed directly on a flat perforated plate, machined from forged stainless steel. The fuel assemblies are centered by two pins each, which are screwed to the core plate. The cooling water flows through the core plate through four holes dedicated to each fuel assembly. The space between the polygonal outer shape of the core and the cylindrical inner surface of the core barrel is filled by a stainless steel structure to reduce leakage of fast neutrons and to flatten the power distribution. The bulk of the internals is made of low-carbon stainless steel.

The core barrel flange rests on a ledge machined from the flange of the reactor pressure vessel and is preloaded by an elastic system. The fuel assemblies are placed directly on a flat perforated plate, machined from forged stainless steel. The fuel assemblies are centered by two pins each, which are screwed to the core plate. The cooling water flows through the core plate through four holes dedicated to each fuel assembly. The space between the polygonal outer

shape of the core and the cylindrical inner surface of the core barrel is filled by a stainless steel structure to reduce leakage of fast neutrons and to flatten the power distribution. The bulk of the internals is made of low-carbon stainless steel.

The *steam generators* feature an axial economizer to provide a steam pressure increase of about 3 bar when compared to a boiler type of the same heating surface. The material for the heating tubes will be chosen from either Incoloy 800 or Inconel 690. The heating tubes are supported by perforated plates.

The *pressurizer* is of conventional design but with an enlarged free volume. The spray systems for normal operation and auxiliary spray are completely separated from each other. In addition, in order to achieve a life time of 60 a and meet the requirements as regards plant power flexibility, several separate spray lines are provided and operated alternatively.

All pressure boundary parts, except for the heater penetrations, are made of ferritic steel; basically the same as used for the reactor pressure vessel. The penetrations are in stainless steel and welded with an Inconel material.

The *reactor coolant pumps* are of well-proven design, as already used in plants in France and Germany. The reactor coolant pumps are provided with a standstill seal in order to assure leak-tightness of the shaft seal without the need of an active seal water supply system under conditions when the pump is at rest, e.g., in the event of a station blackout.

The *main coolant lines* will either be made from forged ferritic steel with austenitic steel cladding or from forged stainless steel. A high quality and surveillance program enables preclusion of the leak-before-break philosophy. However, a mass flow equivalent to a double ended break of a main coolant line is still assumed when designing the emergency core cooling system.

Operating Characteristics. The EPR is a Nuclear Island (i.e., includes all equipment inside the reactor building and the main reactor auxiliary systems) for a power output of about 1500 MW_e. The primary components are enlarged relative to current types, the safety and operating systems have been redesigned or updated to the conditions required.

The EPR can be operated between 20 and 100 % of rated generator power. In the power range between 50 % and 100 % load, the control systems will keep the average coolant temperature constant in accordance with the so-called part load diagram; the main steam pressure will vary between 8.4 and 7.25 MPa. In the lower power range, below 50 % power, the main steam pressure is kept constant at 8.4 MPa and the average coolant temperature will vary with the load. This control strategy results in the lowest demands on the chemical and volume control system, loads on the pressurizer surge line, and the control rod drive mechanisms during load changes in the most frequent operation mode. In the lower power range, a continuation of the constat average coolant temperature mode would penalize the secondary side design (by a design pressure increase) and eventually also the primary side design pressure. The control and operational systems are designed to provide the EPR with a high capability to follow the actual power demands of the grid.

Reactor Auxiliary Systems. The *chemical and volume control system* has safety-related and operational functions. The safety-related functions aim at providing make-up to the reactor coolant system in the event of loss of inventory due to limited leakages and providing boration capacity up to a concentration as required for cold shutdown under operational and certain accident conditions. In addition, the system provides a means for pressure control of the primary circuit by supplying auxiliary spray to the pressurizer (thereby condensing steam and reducing primary system pressure) and seal water to the reactor coolant pumps.

The operational functions of the system are: control of the water inventory, the water quality, and the boron concentration in the primary system. Additionally, the system adjusts the chemical composition of the reactor coolant system and removes dissolved gases by degasification of the letdown flow.

3.1.1.5.2. Instrumentation and Control Systems

I&C Structure. The I&C systems and equipment are divided into three classes (F1A,

F1B, F2) in accordance with their importance for safety and with respect to required reliability, performance, failure behavior, maintenance, testing, and QA; in addition, there is a nonclassified category (NC). The main features of these categories are:

1) The I&C of the F1A class is used for automatic actuation and control of safety-grade systems. It shall withstand a single failure also during periods of maintenance and testing. In addition, spurious actuation upstream of the last voter is prevented by the fourfold redundant and physically separated safety trains.
2) The I&C of the F1B class has a functional structure that can cope with a single failure – without the additional requirements related to maintenance and testing. Special emphasis is laid on the qualification of the back-up control and information means, including the related software.
3) The I&C of the F2 and NC classes is used for normal operation of the plant, including the control of major plant parameters, limiting conditions of operation (LCOs), information and operation and other nonsafety I&C functions.

Safety I&C (F1). The safety I&C functions must have a high reliability so that they will not be a dominant contributor to the unavailability of safety systems. The safety I&C is of redundant architecture and designed to limit the consequences of equipment failures or malfunctions that may result from failure-inducing events within I&C systems (single failure) and their consequential effects. Connections between redundant trains are necessary for exchange of information and commands, but they must not impair the independence. To this end, the redundant trains, or divisions, are installed with physical separation and with a minimum number of interconnections.

Appropriate measures are provided to cope with common cause failures (CCF) in order to meet the overall probabilistic design targets. CCFs and their consequences can result from different sources (e.g., faulty manufacturing, erroneous design, equipment failures, and environmental conditions during the course of accidents).

Operational I&C. The operational I&C encompasses all I&C functions and associated systems and equipment for normal operation. It includes the measurements, the signal conditioning, open- and closed-loop controls, the signal processing, and the data transfer to the man – machine interface.

The tasks of the open- and closed-loop control are: (1) control of the nuclear power generation during normal operation and anticipated operational occurences in such a way that predetermined setpoints for relevant process variables are reached and maintained; (2) protection of mechanical equipment with high investment costs via redundant equipment protection, and (3) provision of information for displaying the plant status for normal, upset, and accident conditions and for documentation of all relevant process data.

Man – Machine Interface Facilities and Control Rooms. The main control room is a screen-based control room with an overview panel. It is used for process control during normal, or accident situations including outages. In addition, the main control room has a safety control area with back-up control means. Further functions of the main control room or of adjacent rooms are security surveillance, fire protection and radiation monitoring, management of maintenance and periodic testing, external and internal communication, and access to documentation and to recorded information. The main control room accommodates operator work stations (all of the same design) which are used for process control in all plant conditions via operational I&C. A plant overview panel is visible from all work places and will be used for the coordination among the operators.

The safety control area (with the back-up control means) in the main control room is used in the event of major losses of the normal control means. It can be used for the safe shutdown (hot or cold) of the plant or to perform post-accident operation. The EPR is provided with a Remote Shutdown Station (RSS) which is designed for transferring the plant to and maintaining it in safe shutdown conditions, in case of unavailability of the main control. The RSS is equipped with internal and external communication means.

3.1.1.5.3. Safety Concept

Safety Requirements and Design Philosophy. The strategy pursued for the EPR is to further enhance the very high safety level of French and German pressurized-water reactors. This strategy implies improving the prevention of accidents – including severe accidents – and adding features, mainly related to the containment, to mitigate the consequences of postulated severe accident scenarios – including core melt situations – to avoid need for stringent off-site countermeasures. The probability of such postulated accidents has been significantly reduced. The plant design is based on a deterministic approach and considers "risk reduction" measures.

Deterministic Design Basis. In the deterministic analysis the different events are categorized in four Plant Condition Categories (PCCs) in accordance with their anticipated frequency of occurrence; PCC1 covers normal operation states, PCC2 to PCC4 envelop transients, disturbed states, and accidents. Stringent radiological limits are applied for normal operation and anticipated operational occurrences as well as for accidents.

Risk Reduction. The EPR design takes into consideration also events beyond the Deterministic Design Basis (i.e., events with multiple failures and corresponding occurrences up to the total loss of safety-grade systems) on a probabilistic basis in order to quantify the residual risk. Release limits of radioactivity in case of severe accidents have been specified on the basis that no stringent off-site emergency response actions (such as evacuation or resettlement) would be needed outside the immediate vicinity of the plant.

The overall safety objectives that have been set for the EPR require that the probability of core damage (CDF) shall be below 10^{-5}/a; and the probability of large releases to the environment shall be below 10^{-6}/a, including all events and all reactor operating states.

Two Risk Reduction Categories (RRCs) have been introduced and representative scenarios defined for both. RRC-A relates to additional features to prevent accidents from progressing to a core melt situation, and RRC-B to prevention of large releases, in order to provide a design basis for risk reduction features. Typical examples on risk reduction features are:

1) Primary system discharge to the in-containment refueling water storage tank, in the event of total loss of secondary side cooling (RRC-A); and
2) Features for spreading and cooling of corium, for hydrogen recombination, and for containment heat removal in the event of a core melt situation (RRC-B).

External and internal hazards are normally not assigned directly to specific plant condition categories or risk reduction categories, in order to avoid the study of numerous sequences. But the main principles behind the deterministic design basis and the risk reduction approach (namely: the more probable the event, the more conservative rules and acceptance criteria) are applied also for dealing with external and internal hazards.

External hazards are to a certain extent site--dependent. Sites with an extreme external hazard potential are not taken into consideration as potential sites.

Safety Systems and Features (Active and Passive).

Safety Systems Configuration. Important safety systems (safety injection, emergency feedwater, main steam relief, cooling chain, emergency electric power) are arranged in a four-train configuration (see Fig. 29). The layout comprises four separate divisions, corresponding to the four trains.

The safety injection systems (see Table 16), feature an In-containment Refueling Water Storage Tank (IRWST) located at the bottom of the containment. During design basis accidents the low-head safety injection (LHSI) system transfers the decay heat to the ultimate heat sink via heat exchangers. The containment spray system is only used for heat removal in case of severe accidents. The delivery head of the medium head safety injection (MHSI) system will be adjusted below the steam generator relief and safety valve set points. In case of a steam generator tube rupture, the affected steam generator will be isolated on the secondary side. After the initial transient, the primary and secondary pressures will equalize at a level below the set points of the safety valves in this steam generator.

Figure 29. EPR – Configuration of fluid safety system

Table 16. Organization of safety injection systems

Medium head safety injection system	4 trains, cold side injection
Accumulators	4 accumulators, cold side injection
Low head safety injection system	4 trains, cold side injection (short term); combined hot /cold injection (long term)
Residual heat removal system	2 trains, independent from safety injection system
In-containment refueling water storage tank	storage of borated water inside containment

A separate residual heat removal (RHR) system is provided, arranged in two trains and installed inside the containment to minimize risk of containment bypass.

The function of any one of the safety systems can be accomplished by another diverse system (or group of systems) during malfunction. Special design provisions are devoted to preventing the high pressure core melt. Therefore, highly reliable secondary side heat removal systems are implemented.

Safety Injection Systems. The safety injection systems mitigate loss of coolant accidents of all sizes, specific non-LOCA events, such as breaks of main steam lines, and sequences leading to feed and bleed. The systems ensure heat removal, coolant inventory, and reactivity control.

The medium head safety injection (MHSI) system feeds into the cold legs of the reactor coolant system. The shut-off head of the system is 8.0 MPa, which is sufficient to cope with all LOCA related requirements.

In addition to the medium head injection system, cold leg accumulator injection is provided to cope with large and intermediate break sizes. Four accumulators with a volume of 50 m^3 each are provided, each directly assigned to one cold leg. The response pressure of the accumulators is designed to 4.5 MPa.

The *low pressure injection system* feeds initially into the cold leg. In order to stop the core outlet steaming and the steam release into the containment, after 1 – 2 h combined injection into the hot and cold legs starts. The injection pressure of 2.5 MPa offers advantages for feed and bleed operation and supports accumulator injection in an optimum way for a large spectrum of break sizes.

In-Containment Refueling Water Storage Tank. The in-containment refueling water storage tank is located inside the containment between the reactor cavity and the missile protection cylinder on the bottom level of the containment. In the case of loss of coolant accidents, or in feed and bleed situations, the safety injection system draws from the in-containment refueling water storage tank. The water steam mixture escaping through the leak and through the bleed valve, respectively, is returned to the tank. In the case of severe accidents the in-containment water storage tank will provide the cooling water

for flooding the spread molten corium. In addition, the storage tank provides water for the operational function of flooding the reactor pit and the pools during refueling.

Emergency Feedwater System. The emergency feedwater system (only safety grade, see Fig. 30) consists of four separate and independent trains, each providing injection to one of the four steam generators. Each emergency feedwater pump takes suction from an emergency feedwater tank. These tanks and the systems are located in the four divisions of the safeguard buildings.

The emergency feedwater system transfers the residual and latent heat from the reactor coolant system via the steam generators to the atmosphere as long as the steam generator saturation temperature is above 150 °C, following any plant incident or accident other than those reactor coolant boundary ruptures for which complete residual heat removal by the safety injection system is possible (i.e., moderate to large size loss of coolant accidents). Following a LOCA not all core residual heat is released through the break flow and at least a portion of the heat must be removed via the steam generators, the emergency feedwater system ensures sufficient water supplies to the steam generators.

In the case of a steam generator tube rupture, the emergency feedwater system removes the heat via the intact steam generators.

The emergency feedwater system keeps the water inventory of at least one steam generator above an adequate level to maintain primary to secondary heat transfer, assuming a single failure. Safety grade, i.e., normally locked closed headers, can only be opened after a certain grace period for pressure reduction in the unfed steam generator.

After a small break LOCA or a steam generator tube rupture, the emergency feedwater system provides enough cooldown capability that the saturation pressure of the steam generator of 6.0 MPa is reached within a time span consistent with the performance requirements of the safety injection system and the radioactivity release limits for steam generator tube rupture, assuming a single failure.

The emergency feedwater system shall provide sufficient heat removal capacity and autonomy to ensure continued removal of decay heat for 24 h with a final reactor coolant system temperature not exceeding nominal hot shutdown conditions.

Residual Heat Removal System. The residual heat removal system combines operational and safety functions. The safety function implies that the residual heat removal system, in conjunction with the component cooling water system and the service water system, shall maintain the reactor coolant system core outlet and hot leg temperature below 180 °C following a reactor shutdown, assuming a single failure and the maximum design temperature of the service water. The operational function requires the residual heat removal system to be capable of cooling down the reactor coolant system to 50 °C following a reactor shutdown, with at least one reactor coolant pump in operation and considering the maximum design temperature of the service water. The residual heat removal system consists of two separate and independent trains located inside the containment. During normal operation, only the inside RHR trains are used for cooldown and cold shutdown. Back-up trains are not used unless the RCS temperature is below 100 °C.

In case of a total loss of both residual heat removal trains, the residual heat removal function can be taken over by two of the four low head safety injection trains, which function as a back-up for the residual heat removal system.

Severe Accidents (Beyond Design Basis Accidents). The EPR design enhances accident prevention and reduces the residual risk for the public and the environment by reducing possible releases of radioactive material and radiological consequences arising from severe core damage sequences. The design target of the EPR is that off-site emergency response actions (population evacuation or relocation) shall be restricted to the nearby plant vicinity. To this end, maintaining the integrity of the containment is utterly important. this can be achieved by:

Avoiding early containment failure or bypass
Cooling of the corium in the containment and retention of fission products by covering with water
Preservation of containment functions, such as low leak rates, reliable isolation function, prevention of basemat melt-through, and ultimate pressure resistance to cope with energetic events

Figure 30. EPR – Configuration of emergency feeedwater system

Pressure reduction inside the containment by dedicated heat removal
Collection of unavoidable containment leakages in the annulus atmosphere and release via stack after filtration

Severe Accident Prevention and Mitigation Features. The EPR strategy includes both preventive measures and mitigating features:

1) Prevention of high pressure core melt situations, by ensuring a high reliability of the decay heat removal systems, complemented by pressurizer relief valves. The depressurization eliminates high pressure failure of the RPV and the danger of direct containment heating with the potential consequence of early containment failure. The consequences of an instantaneous full cross-section break of the RPV at a pressure of about 2.0 MPa are nevertheless taken into account for the pit layout and support design.
2) Prevention of formation or reduction of the hydrogen concentration in the containment by catalytic H_2-recombiners and, if necessary, by selectively arranged igniters. The prevention of molten core–concrete interaction contributes to reducing the amount of hydrogen.
3) Prevention of ex-vessel steam explosions endangering the containment integrity by minimizing the amount of water in the area where the corium is spread.
4) Prevention of a molten core–concrete interaction by spreading the corium in a spreading compartment provided with a protective layer, and
5) Connection of this spreading compartment to the reactor pit via a melt discharge channel which slopes towards the spreading compartment. This channel is closed by a steel plate (possibly covered with refractory material) which will resist melt-through for a certain time, in order to accumulate the melt in the pit.
6) Provisions for connecting the spreading compartment with the In-Containment Refueling Water Storage Tank (IRWST) for water flooding after spreading; these pipe connections are closed during normal operation.

7) Dedicated basemat cooling system supplied by the containment heat removal system to prevent high temperature loadings in the basemat.

3.1.1.5.4. Plant Layout

Buildings and Structures, Including Plot Plan. The general layout of the EPR plant (plot plan) is shown in Figure 31. The reactor building with the containment is surrounded by the safeguard and fuel buildings which contain safety systems. Most of the safety-grade systems are designed with a four-fold redundancy, arranged in four independent divisions with complete physical separation.

Other plant buildings, such as the access building and the nuclear auxiliary building, are located in close contact with the safeguard and fuel buildings, whereas the turbine building and the associated conventional electrical building are built separate from the reactor building complex and arranged such that the reactor building is located in the projection of the turbine generator shaft.

Design Requirements. The plant is designed to withstand the impacts of internal and external events. With respect to earthquake and explosion pressure waves, the buildings and structures have been strengthened so that the function of safety-grade equipment will not be jeopardized by collapsing structures, and the equipment itself must withstand the dynamic effects inside the buildings. For protection against airplane crash, safety-related equipment is located in bunkers, or redundant portions will be geographically separated from each other so that only one train is affected.

Table 17. Boiling-water reactors in the Federal Republic of Germany

Plant	Gross output, MW_e	Handover	Decom-missioned
Kahl	16	1962	1985
Gundremmingen A	250	1966	1980
Lingen	267	1968	1977
Würgassen	670	1975	
Brunsbüttel	806	1976	
Isar 1	907	1979	
Phillippsburg 1	900	1980	
Krümmel	1316	1984	
Gundremmingen B	1300	1984	
Gundremmingen C	1308	1985	

The loads from internal events (e.g., fire loads, missile loads, jet impingement loads, flooding effects) are covered by design features (e.g., four-train four-division concept).

Reactor Building (Containment). The reactor building (cf. Figure 32, main building complex) is the central building of the plant complex. It coincides completely with the containment, and thus, the following description of the containment covers also the reactor building.

Adoption of a double concrete containment design was decided for the EPR. The inner containment wall is made of prestressed concrete. The leak-tightness requirement of less than 1 vol % per day can be ensured without provision of a containment liner. The outer wall, in reinforced concrete, completes the double containment arrangement. Leakages through the inner containment wall are released via the annulus air extraction system. Openings for access of personnel or supply of equipment to the inside of the containment are permanently closed hatches or air locks

Table 18. Characteristic data for boiling-water reactors manufactured in the Federal Republic of Germany

	Name/Location				
Characteristic data	Kahl	Lingen	Würgassen	Brunsbüttel	Gundremmingen C
Overall plant					
Start of commercial operation	11/61	10/68	11/75	2/77	1/85
Thermal output, MW_t	60	516 + 216 [a]	1912	2292	3840
Net electric output, MW_e	15	240	640	771	1308
Net efficiency, %	24.8	32.6	33.4	33.6	32.5
Direct cycle			yes	yes	yes
Indirect cycle	yes	yes			
Reactor core					
Uranium mass, t	5	32	81	97	139
Fuel	enriched UO_2, UO_2-PuO_2	enriched UO_2, UO_2-ThO_2	enriched UO_2	enriched UO_2	enriched UO_2
No. of fuel assemblies	88	284	444	532	784
No. of fuel rods per assembly	36	36	63	63	62
Outside diameter of fuel rod, mm	14.3	14.3	12.5	12.5	12.3
Average specific power, kW/kg U	11.3	16.1	23.5	23.5	26.5
No. of control rods	21	69	109	129	193
Nuclear steam supply system					
Coolant core outlet temperature, °C	286	286	286	286	286
Coolant pressure, MPa	7.06	7.06	7.06	7.06	7.06
No. of recirculation pumps	natural circulation	2 external [b]	2 external 16-jet pumps [c]	8 internal [d]	8 internal [d]
Turbine					
Main steam pressure, MPa	4.7	4.2	6.57	6.57	6.7
Main steam temperature, °C	259	530	281.5	281.5	283

[a] Additional fossil-fired superheater (216 MW_t) in secondary cycle.
[b] Reactor water recirculated outside RPV.
[c] Eight jet pumps in RPV receive motive water from one external pump.
[d] Axial-flow recirculation pump inside RPV.

with double sealings on both sides. Fluid systems penetrating the containment are provided with double isolation valves, inside and outside the containment.

Accumulation of combustible gases, especially hydrogen, is controlled. Furthermore, the basemat in the spreading compartment is protected by protective layers and the dedicated cooling system which is fed by the containment heat removal system against elevated temperatures resulting of a core melt.

The severe accident conditions lead to more severe design conditions compared to existing plants. Most important is the increased design pressure of 650 kPa.

Other Buildings.

Safeguard and Fuel Buildings. Connections between the safety systems and the reactor coolant system are made as short as possible. The individual trains of the safety systems are arranged radially to the primary loops.

The four trains of the safety systems are located in four safeguard buildings that surround the reactor building.

The storage pool for spent fuel assemblies is located outside the containment, facilitating loading and unloading of the fuel transport cask for the transport of fresh fuel to the plant and of spent fuel away from the plant. A transfer tube in the containment wall connects the inside of the containment with the fuel building.

The primary system is arranged symmetrically. Concrete walls are provided between the loops and between the hot and cold legs of each loop to provide protection against consequential failures. The pressurizer is located in a separate compartment. A concrete wall around the entire primary system protects the containment from impact of missiles and reduces the radiation from the primary system to the surroundings.

A water pool for storage of the upper core internals during refueling and for the entire core internals during inspection, is located inside the containment for radiation protection reasons.

3.1.1.5.5. Technical Data

General plant data	
Power plant output, gross, MW_e	1500
Reactor thermal output, MW_{th}	4250
Reactor coolant system	
Primary coolant flow rate, kg/s	21900
Reactor operating pressure, MPa	15.5
Coolant inlet temperature, at RPV inlet, °C	291
Coolant outlet temperature, at RPV outlet, °C	327
Reactor core	
Active core hight, m	4.2
Average linear heat rate, kW/m	15.5
Fuel material	sintered UO_2
Fuel assembly total length, mm	4800
Rod array	square, 17×17
Number of fuel assemblies	241
Number of rods per assembly	264
Number of control rod guide tubes	25
Number of spacers	9
Enrichment (range) of first core, wt %	≤ 5.0
Operating cycle length (fuel cycle length), months	18 (12, 24)
Average discharge bunup of fuel, MW · d/t	60000
Cladding tube material	Zr 4
Cladding tube wall thickness, mm	0.725
